## Commonly Used Descriptors

- Haplotype Frequencies
- The frequency of each type of chromosome
- Contain all the information provided by other summary measures
- Commonly used summaries
${ }^{\circ}$ D
${ }^{\circ}$ D'
- $r^{2}$ or $\Delta^{2}$

## Haplotype Frequencies

## Linkage equilibrium expected for distant loci

## Linkage equilibrium expected for nearby loci

Fill out this table.
X 11 is number of times that haplotype is seen.

|  | 2818 <br> C | 2818 <br> T |  |
| :---: | :---: | :---: | :---: |
| 3027 <br> T | X11 | X21 | \# 3027 T <br> alleles |
| 3027 <br> C | X12 | x22 | \#3027 C <br> alleles |
|  | \# 2818 C <br> Allele | \# 2818 T <br> allele |  |

## Allele Counts

## Haplotype frequencies

## Disequilibrium Coefficient $D_{A B}$

## $D_{A B}$ is hard to interpret

- Sign is arbitrary ...
${ }^{\circ}$ A common convention is to set $A, B$ to be the common allele and $a, b$ to be the rare allele
- Range depends on allele frequencies
- Hard to compare between markers

## $D^{\prime}$ - a scaled version of $D$

## More on $D^{\prime}$

- Pluses:
${ }^{-} \mathrm{D}^{\prime}=1$ or $\mathrm{D}^{\prime}=-1$ means no evidence for recombination between the markers
- If allele frequencies are similar, high D' means the markers are good surrogates for each other
- Minuses:
- D' estimates inflated in small samples
- D' estimates inflated when one allele is rare

## Correlation coefficient R

## More on $\mathbf{r}^{\mathbf{2}}$

- $r^{2}=1$ implies the markers provide exactly the same information
- The measure preferred by population geneticists
- Measures loss in efficiency when marker A is replaced with marker B in an association study
- With some simplifying assumptions (e.g. see Pritchard and Przeworski, 2001)

## Summarizing Disequilibrium

## Comparing Populations

LD extends further in CEPH and the Han/Japanese than in the Yoruba

## Compare observed and expected frequencies

This calculator compares observed and expected frequencies with the chi-square test. Read an example with explanation.

Note that the chi-square test is more commonly used in a very different situation -- to analyze a contingency table. This is appropriate when you wish to compare two or more groups, and the outcome variable is categorical. For example, compare number of patients with postoperative infections after two kinds of operations. If you need to analyze a contingency table, do not use this table. If you have two groups (rows) and two outcomes, use this calculator. If your table is larger, try the free demos of GraphPad InStat (basic statistics only) and GraphPad Prism (statistics, nonlinear regression and scientific graphics).

Enter the names of the categories into the first column (optional). Enter the actual number of objects or individuals or events observed in the second column. Then enter the expected number, fraction or percent expected in the third column.

## Stuart's genotype

## browse raw data

Showing raw data for SNP rs6983267, which is on chromosome 8.

| Gene | Position | SNP | Versions | stuart kim's Genotype |
| :--- | :--- | :--- | :--- | :--- | :--- |
| H intergenic | 128482487 | rs6983267 | G or T | GG |

Homozygous bad allele $\square$

## How different is this SNP in the cases versus the controls?

Allelic odds ratio: ratio of the allele ratios in the cases divided by the allele ratios in the controls

Likelihood ratio: Given a genotype, how much more likely are you to show a trait compared to the general population

## Multiple hypothesis testing

"Of the 547,647 polymorphic tag SNPs, 27,673 showed an association with disease at $\mathrm{P}<.05$."

- $P=.05$ means that there is a $5 \%$ chance for this to occur randomly.
- If you try 100 times, you will get about 5 hits.
- If you try 547,647 times, you should expect $547,647 \times .05=27,382$ hits.
- So 27,673 (observed) is about the same as one would randomly expect.

## Multiple hypothesis testing

"Of the 547,647 polymorphic tag SNPs, 27,673 showed an association with disease at $\mathrm{P}<.05$."

- Here, have 547,647 SNPs = \# hypotheses
- False discover rate = q = p x \# hypotheses. This is called the Bonferroni correction.
- Want $q=.05$. This means a positive SNP has a .05 likelihood of rising by chance.
- At $q=.05, p=.05 / 547,647=.91 \times 10^{-7}$
- This is the $p$ value cutoff used in the paper.

## Multiple hypothesis testing

"Of the 547,647 polymorphic tag SNPs, 27,673 showed an association with disease at $\mathrm{P}<.05$."

- The Bonferroni correction is too conservative. It assumes that all of the tests are independent.
- But the SNPs are linked in haplotype blocks, so there really are less independent hypotheses than SNPs.
- Another way to correct is to permute the data many times, and see how many times a SNP comes up in the permuted data at a particular threshold.

Fill out this table.
Convert all numbers to frequencies.

\begin{aligned}
D_{A B} & =p_{A B}-p_{A} p_{B} \\
p_{A B} & =p_{A} p_{B}+D_{A B} \\
p_{A b} & =p_{A} p_{b}-D_{A B} \\
p_{a B} & =p_{a} p_{B}-D_{A B} \\
p_{a b} & =p_{a} p_{b}+D_{A B}
\end{aligned}
$$

## D' - A scaled version of D

$$
D_{A B}^{\prime}= \begin{cases}\frac{D_{A B}}{\min \left(p_{A} p_{B}, p_{a} p_{b}\right)} & D_{A B}<0 \\ \frac{D_{A B}}{\min \left(p_{A} p_{b}, p_{a} p_{B}\right)} & D_{A B}>0\end{cases}
$$

- Ranges between -1 and +1
- More likely to take extreme values when allele frequencies are small
- $\pm 1$ implies at least one of the observed haplotypes was not observed

## $\Delta^{2}$ (also called $\mathbf{r}^{2}$ )

$$
\begin{aligned}
\Delta^{2} & =\frac{D_{A B}^{2}}{p_{A}\left(1-p_{A}\right) p_{B}\left(1-p_{B}\right)} \\
& =\frac{\chi^{2}}{2 n}
\end{aligned}
$$

- Ranges between 0 and 1
- 1 when the two markers provide identical information
- 0 when they are in perfect equilibrium
- Expected value is $1 / 2 n$

Cancer: 0.57G 0.43T
Cancer: G:T ratio $=0.57 / .43=1.32$
controls: 0.49G 0.51T
controls: G:T ratio = .49/.51 = . 96

Allelic odds ratio $=1.32 / .96=1.37$
