Abstract—We present a method for the automatic compositional verification of certain classes of concurrent programs. Our approach is based on the casting of the model checking problem into a theory of transition systems within CVC4, a DPLL(T) based SMT solver. Our transition system theory then cooperates with other theories supported by the solver (e.g., arithmetic, arrays), which can help accelerate the verification process. More specifically, our theory solver looks for known patterns within the input programs and uses them to generate lemmas in the languages of other theories. When applicable, these lemmas can often steer the search away from safe parts of the search space, reducing the number of states to be explored and expediting the model checking procedure. We demonstrate the potential of our technique on a number of broad classes of programs.

I. INTRODUCTION

In concurrent programming, the size of the composite program is typically exponential in the number of its constituent threads. This phenomenon, an instance of the state explosion problem, is a major hindrance to the verification of concurrent software. In recent decades, a prominent approach to tackling this difficulty has been that of compositional verification [13]: properties of threads are derived/verified in isolation, and are used to deduce global system correctness, without exploring the entire composite state space. When applicable, compositional verification can often significantly outperform direct verification techniques.

A key challenge in compositional verification is how to automatically come up with "good" thread properties — those whose verification is considerably cheaper than the verification of the global property on the one hand, but which are sufficiently meaningful to imply the desired system properties on the other. Automatic property generation is essential in rendering a compositional verification scheme scalable [11].

Since the compositional verification of arbitrary programs is difficult (and often impossible [9]), one reasonable approach is to trade generality for effectiveness — i.e., to limit the scope of programs that a scheme handles, in exchange for better performance on programs that remain within that scope. Here, we adopt this approach and propose an automatic compositional verification scheme for certain kinds of concurrent software.

The paper has two main contributions. The first is the rigorous formalization and implementation of a solver for a theory of transition systems (TS) within the context of CVC4 [1] — a lazy, DPLL(T) based SMT solver [28]. The TS solver takes as input formulas describing a program’s concurrent threads (given as transition systems) and the assertion that a certain safety property is violated; and it answers UNSAT if the program is safe, or SAT if it is not. As a standalone module, the TS solver explores the space of reachable states in order to determine a system’s safety — an exploration that is driven by the SMT solver’s underlying SAT engine.

Several existing approaches utilize SMT solvers in model checking (e.g., Lazy Annotation [26] and PDR [8]), but typically the process is driven by a model checker that uses an SMT solver as a black-box tool. In our approach the roles are reversed, and the SMT engine, via the TS solver, can be regarded as invoking a model checker. This design allows other theories within CVC4 to be seamlessly used in analyzing the input program at hand, determining which parts of the state space should be explored and which may safely be ignored. These theories may then influence the search conducted by the TS solver by asserting lemmas to the underlying DPLL(T) core, sometimes pruning significant portions of the search space and greatly improving performance. We term this process theory-aided model checking: the TS solver explores the state space while also looking for opportunities in which other theories may aid and direct the search.

The second contribution of the paper is in the way other theories determine which parts of the state space may be ignored during model checking. We perform this by having the TS solver analyze the input threads and look for pre-supplied patterns: structural properties of the threads that may be expressed as assertions in the languages of other theories, such as arithmetic or arrays. It is through these assertions that other theories can “understand” the program and efficiently discover, e.g., that a certain branch of the search space cannot lead to a violation. A key fact here is that each thread/transition system is analyzed separately — and hence the compositionality of our approach: the analysis complexity is proportional to the size of the program and not to that of its state space. We thoroughly describe three of the currently implemented patterns.

While our proposed technique is compositional and completely automatic, it is useful only when the input programs match one of the pre-supplied patterns. This is in line with our approach of trading generality for effectiveness, and, as we demonstrate in later sections, our approach is capable of effectively handling broad classes of programs even with just a few stored patterns.

The type of software that we target here is a family of discrete event systems. In particular, we focus on a computational model that has three fundamental concurrency idioms — requesting events, waiting-for events and blocking events — which we term the RWB model. The RWB concurrency idioms are widespread and appear, sometimes
in related forms, in various formalisms such as publish-subscribe architectures [12], supervisory control [29] and live sequence charts (LSC) [10]. Together, these three idioms also form the behavioral programming (BP) framework [20]. Thus, by focusing on the RWB model, we hope to make our technique applicable (with appropriate adjustments) to a variety of programming formalisms. Further, we believe that the technique can be extended to cater to additional concurrency idioms and models.

The rest of the paper is organized as follows. In Section II we recap the definitions of the DPLL(T) framework for SMT solvers and of the RWB model. Next, in Section III we introduce the theory of transition systems (TS) and describe a theory solver aimed at model checking RWB programs. In Section IV we demonstrate how the TS solver can cooperate with other theory solvers in order to expedite model checking. Subsequently, we apply our technique to two broad classes of problems: periodic problems in Section V, and programs with shared arrays in Section VI. Experimental results appear in Section VII, and we conclude with a discussion and related work in Section VIII.

II. DEFINITIONS

The DPLL(T) Framework. DPLL(T) [28] is an extensible framework used by modern SMT solvers. It employs multiple specialized theory solvers that interact with a SAT solver. The SAT solver maintains an input formula $F$ and a partial assignment $M$ for $F$. Periodically, a theory solver is asked whether $M$ is satisfiable in its theory; and, if it is not, the theory solver generates a conflict clause, the negation of an unsatisfiable subset of $M$, that is added to $F$. The theory solver may request case splitting by means of the splitting-on-demand paradigm [2], which allows the solver to add theory lemmas to $F$ consisting of clauses possibly with literals not occurring in $F$.

The RWB Model. In this work we focus on the RWB model for concurrent discrete event systems. An RWB program is comprised of a set of events and set of threads that communicate via the requesting, waiting-for and blocking of events. More specifically, the threads repeatedly synchronize with each other at predetermined synchronization points, and at each such point they each declare events that they request and events that they block. Then, an event that is requested by at least one thread and not blocked is selected for triggering, and all the threads that requested or waited-for this event proceed with their execution. Whenever a new synchronization point is reached, the process is repeated.

The RWB model is not intended to be programmed in directly. Rather, it is used to describe the underlying transition systems of threads written in higher level languages, for the purpose of analysis and verification. Actual programming in RWB is performed, e.g., using the behavioral programming (BP) framework [20], which is implemented in various high level languages such as C++ or Java (see http://www.b-prog.org). Thus, while inter-thread communication in BP is performed solely through the RWB idioms, threads may internally use any construct provided by the underlying programming language (e.g., C++). Indeed, the tool and examples described in this paper were prepared using a C++ version of BP (termed BPC [16]), and CVC4. It should further be noted that the RWB definitions as given here entail global lockstep synchronization between components, which may cause unwanted overhead. There exist extensions to RWB that mitigate this difficulty without altering the model’s semantics [14], and our technique is applicable to these extensions as well.

Formally, an RWB-thread $T$ over event set $E$ is a tuple $T = (\delta, \delta_0, R, B)$, where $Q$ is a set of states (one for each synchronization point), $q_0$ is the initial state, $R : Q \rightarrow 2^E$ and $B : Q \rightarrow 2^E$ map states to events requested and blocked at these states (respectively), and $\delta : Q \times E \rightarrow 2^Q$ is a transition function (the definition is adopted from [19]).

RWB programs are created by composing RWB-threads. The parallel composition of threads $T^1 = (Q^1, \delta^1, q_0, R^1, B^1)$ and $T^2 = (Q^2, \delta^2, q_0^2, R^2, B^2)$, both over the same event set $E$, yields the RWB-thread defined by $T^1 || T^2 = (Q^1 \times Q^2, \delta, (q_{01}, q_0^2), R^1 \cup R^2, B^1 \cup B^2)$, where $\delta^1 \in \delta(\delta^1, q_{02})$, $\delta_2 \in \delta(\delta^2, q_{01})$. The union of the labeling functions is defined in the natural way, i.e. $e \in (R^1 \cup R^2)((\delta_1, q_{12}))$ if $e \in R^1(q_1) \cup R^2(q_2)$. An RWB program $P$ comprised of RWB-threads $T^1, T^2, \ldots, T^n$ is the composite thread $P = T^1 || \ldots || T^n$.

Denoting $P = (Q, \delta, q_0, R, B)$, an execution of $P$ starts from $q_0$, and in each state $q$ along the run an enabled event is chosen for triggering, if one exists (i.e., an event $e \in R(q) \setminus B(q)$). Then, the execution moves to state $\tilde{q} \in \delta(q,e)$, and so on. An execution can either be infinite, or finite if it ends in a state with no successors (a deadlock state). An illustration of a simple RWB program appears in Fig. 1.

![Figure 1: An RWB program for controlling the water level in a tank with hot and cold water sources. Each node corresponds to a synchronization point in a thread, labeled with its requested (R) and blocked (B) events. Waiting-for events are not labeled, and are represented by transitions. If an event that a thread did not wait for is triggered, the thread does not change states. In the program depicted, the RWB-thread WhenLowAddCold repeatedly waits for WaterLevelLow events (requested by a sensor thread, not shown) and requests three times the event Hot. WhenLowAddCold performs a similar action with the event Cold. In order to keep the water temperature stable, the Alternation thread enforces the interleaving of Hot and Cold events by using event blocking.](image-url)

From a software-engineering perspective, the motivation for using the RWB idioms for inter-thread communication lies in the model’s strict and simple synchronization mechanism. Studies show that this form of inter-thread interaction — i.e., through repeated synchronization and declaration of requested, waited-for and blocked events — facilitates incremental, non-intrusive development, and the resulting systems often have threads that are aligned with the specification [20].

Verifying RWB Programs. In [19], [22], the authors demonstrate how the transition systems underlying RWB-
threads can be automatically extracted from high level code and then, using abstraction techniques, be symbolically traversed in order to verify safety properties. Safety properties are themselves expressed by marker RWB-threads, marking that a violation has occurred with a special API call [19]. For simplicity, we assume that marker threads signal that a violation has occurred by blocking all events, causing a deadlock. Thus, safety checking is reduced to checking for deadlock freedom.

The manual compositional verification of RWB programs is discussed in [15]. There, it is shown how the simple RWB synchronization mechanism facilitates the generation of individual thread properties, which are then used for proving the system property at hand. The beneficial effect that simple concurrency idioms have on verification is also discussed in [18]. Indeed, the simplicity of the RWB idioms plays a key role in the pattern matching algorithm that we discuss later.

III. THE THEORY OF TRANSITION SYSTEMS

We now cast the model checking of RWB into a DPLL(T) setting, by defining a dedicated theory of transition systems (TS). We assume familiarity with the definitions of many-sorted first order logic (see, e.g., [3]). The theory is parameterized by a set \( Q = \{ Q_1, \ldots, Q_n \} \) of state sorts used to represent the state sets of the program’s constituent threads. Let \( Q^+ \) denote the composite state sorts obtained by taking the Cartesian product of one or more elements in \( Q \). Every element \( Q \in Q^+ \) is a sort in TS. Further, every such \( Q \) is also associated with a matching transition system sort, \( S_Q \).

Finally, TS has an event sort, \( E \).

For every \( Q \in Q^+ \) the signature includes the predicate \( I_Q : S_Q \times Q \), indicating initial states; the predicates \( R_Q, B_Q : S_Q \times Q \times E \) to indicate whether an event is requested \((R_Q)\) or blocked \((B_Q)\) at a given state; and the predicate \( Tr_Q : S_Q \times Q \times E \times Q \) to indicate the state transition rules.

In order to reason about composite transition systems, the signature includes the following functions and predicates.

For every \( Q_1, Q_2 \in Q^+ \) we have the transition system function \( q_1 q_2 : S_Q \times Q_2 \rightarrow S_Q \times Q_2 \) (Recall that \((Q_1 \times Q_2)^+\) is itself a sort in \( Q^+ \)); and the pair function \( \text{pair} : Q_1 \times Q_2 \rightarrow (Q_1 \times Q_2) \) function for composing states, which, per the TS semantics, is a bijection. Later we often omit the \( Q \) subscripts when clear from the context.

For each \( Q_1, Q_2 \in Q^+ \), TS has the following axioms which enforce the RWB composition rules. A composite state is initial iff its components are initial states:

\[
\forall s_1 : S_{Q_1}, s_2 : S_{Q_2}, s : S_{Q_1 \times Q_2}. \; s = s_1 \parallel s_2 \implies q : Q_1 \times Q_2, (I(s, q) \iff \exists q_1 : Q_1, q_2 : Q_2, (I(s_1, q_1) \land I(s_2, q_2) \land q = \text{pair}(q_1, q_2))).
\]

Composite transitions are performed component-wise:

\[
\forall s_1 : S_{Q_1}, s_2 : S_{Q_2}, s : S_{Q_1 \times Q_2}. \; s = s_1 \parallel s_2 \implies q, q' : Q_1 \times Q_2, e : E. \; (Tr(s, q, e, q') \iff \exists q_1, q_2 : Q_1, q_2 : Q_2. \; (q = \text{pair}(q_1, q_2) \land q' = \text{pair}(q_1, q_2) \land Tr(s_1, q_1, e, q'_1) \land Tr(s_2, q_2, e, q'_2))).
\]

Requested and blocked events in a composite state are the union of those in the component states:

As previously discussed, by encoding safety properties as threads of the program to be checked, safety is reduced to deadlock freedom. For each \( Q \in Q^+ \), the signature includes a \text{deadlock}_Q : S_Q \times Q \) predicate, such that:

\[
\forall s : S_Q, q : Q. \; (\text{deadlock}(s, q) \iff -\exists q' : Q, e : E. \; Tr(s, q, e, q') \land R(s, q, e) \land -B(s, q, e)),
\]

and the \text{safe_state}_Q : S_Q \times Q \) predicate, with:

\[
\forall s : S_Q, q : Q. \; -\text{safe_state}(s, q) \implies \text{deadlock}(s, q) \lor
\exists q' : S_Q, e : E. \; (Tr(s, q, e, q') \land R(s, q, e) \land -B(s, q, e) \land -\text{safe_state}(s, q')).
\]

The Theory Solver. Inputs for the TS solver start with a \text{preamble} \( \Phi \) that contains assertions that describe the program’s threads. Specifically, \( \Phi \) includes variables \( s_1, \ldots, s_n \), each of sort \( S_Q \) for some basic state sort \( Q \in Q \); and for every \( s_i \) it includes assertions describing its initial states, its transitions and its requested and blocked events. After \( \Phi \), the solver expects an assertion \( \Phi \) about the system’s safety:

\[
\forall s : S_Q. \; -\text{safe}(s) \implies \exists q : Q. \; I(s, q) \land -\text{safe_state}(s, q).
\]

IV. AUTOMATIC ANALYSIS OF TRANSITION SYSTEMS

The calculus in Section III captures the basic proof strategy of our theory solver: a forward reachability search. We next enrich this basic strategy with additional derivation rules, aimed at narrowing down the state space that needs to be explored. The idea is to include within the TS solver a database of \text{structural patterns} that characterize common/useful threads and alongside each pattern also to keep lemmas that describe these threads’ behavior in the language of some other theory.

\footnote{While we do not assume the system is finite-state, we do assume that the initial states and the successors for each state are finite and decidable.}
The program has three threads, depicted in Fig. 4. The safety result, indicating that the system is unsafe.

Next, Decide is invoked for state \(q_1\), generating the assertion \(\neg \text{safe}_\text{state}(s, q_2)\) — followed by the lemma \(\neg \text{deadlock}(s, q_2)\). Decide is then invoked for state \(q_2\), generating \(\neg \text{safe}_\text{state}(s, q_3)\) and the lemma \(\neg \text{deadlock}(s, q_2)\). At this point, the conditions for the \textsc{unsat} rule are met, and the solver closes this branch of the tree. The solver backtracks to the last nondeterministic split and generates the assertion \(\neg \text{safe}_\text{state}(s, q_3)\). State \(q_3\) is deadlock, and so the \textsc{deadlock lemma} rule is not invoked. No additional derivation rules apply, and so the process terminates with a SAT result, indicating that the system is unsafe.

in CVC4. As the \(()}\) solver traverses the state space, it also repeatedly checks to see if any of the patterns apply to the threads at hand. When a match is found, the solver asserts the matching lemmas to the SMT framework. Sometimes, these lemmas may be contradictory to the assertion that the safety property is violated along the current search path, and another theory solver will raise a conflict: this will cause the \(()}\) solver to backtrack and check other areas of the state space.

We demonstrate the method on a simple example, adopted from [15]. Observe an \(RWB\) program over event set \(E = \{0, 1\}\) that generates the event sequence \((0^3 \cdot (0 + 1))^\omega\). The program has three threads, depicted in Fig. 4. The safety property to be verified is that event 1 is never triggered (and so, the program is unsafe). Observe that direct model checking of this system requires visiting 6 composite states.

<table>

</thead>
<tbody>
<tr>
<td>0</td>
<td>0</td>
<td>0</td>
</tr>
<tr>
<td>1</td>
<td>0</td>
<td>1</td>
</tr>
</tbody>
</table>

The key observation is that through the automatically generated lemma, the 4 intermediate states between state \(\langle 0, 0, 0 \rangle\) and \(\langle 1, 2, 0 \rangle\) did not need to be explored. Because the threads matched the looped pattern, CVC4 was able to deduce that these intermediate states would be safe iff state \(\langle 1, 2, 0 \rangle\) was safe. Further, because the arithmetical solver can solve for \(t\) more quickly than the intermediate states can be traversed (especially when generalizing to \((0^n \cdot (0+1))^\omega\) for a large \(n\)), the solver’s performance is improved.

Pattern Matching. The \(()}\) solver’s pattern database consists of pattern matchers. A pattern matcher \(P\) is comprised of a family of recognizer predicates \(\{R_n\}_{n \geq 1}\), where \(R_n\) is defined over \(n\) transition system variables \(s_1, \ldots, s_n\), and determined uniquely by the step index in the run (assuming a violation has not occurred). This is a structural property of each thread, that is checked locally and in isolation from its siblings. After determining that all threads are looped, the solver finds all individual thread states in which 1 is not blocked. In our case, this is state 1 for thread 1, state 2 for thread 2, and state 0 for thread 3. Denoting composite states as triplets, this is state \(\langle 1, 2, 0 \rangle\). Finally, the solver uses the gathered information to generate the following lemma in order to curtail the state space:

\[
\Psi \land \Phi \implies \neg \text{deadlock}(s, q) \quad \text{if } q \text{ has a successor in } s
\]
a lemma generating function \( f \) (described later). For input system \( s = s_1 \parallel \ldots \parallel s_n \), we say that pattern \( P \) applies to \( s \) if \( R_n(s_1, \ldots, s_n) \) evaluates to true. The \( R_n \) predicates can encode various facts about the transition systems: e.g., that threads always or never block certain events, that they have a certain state that must always be revisited, that certain events always send threads into a deadlock state, etc. For example, in the previously discussed looped pattern, \( R_n \) evaluates to true iff each of the threads’ states has precisely one successor state.

In our proof-of-concept C++ implementation, recognizer predicates are coded as Boolean methods that take as input a list (of arbitrary length) of transition systems. Upon receiving a query, the \( TS \) solver passes the input program’s threads to the recognizer predicates of each of the patterns, to determine which patterns apply in this case. Recognizer implementations may traverse the given transition systems, compute strongly connected components, etc. The only restriction, needed for the method to be efficient, is that recognizers do not compute the composite transition systems of the system; they are restricted to (polynomial) operations on the individual threads. Thus, the complexity of pattern matching is polynomial in the size of the individual threads — and because these threads are typically exponentially smaller than the composite program [17], we can quickly test multiple patterns.

The second component in a pattern matcher is the lemma generating function, \( f \). When pattern \( P \) applies to an input program, its lemma generating function is invoked repeatedly during state space traversal, in order to allow \( P \) to generate lemmas that affect the search. Specifically, \( f \) is invoked whenever \( TS \) visits a new state \( q \) (i.e., after the Decide rule generates the assertion \(-safe\_state(s, q)\)), and returns a (possibly empty) list of lemmas concerning the safety of state \( q \). The \( TS \) solver then asserts these lemmas to the underlying SAT engine, and other theories may use them in trimming the search space. In practice, the generated lemmas may depend on parameters extracted from the input threads by the pattern recognizers. For example, in the looped pattern, the size of the loop is extracted by the recognizer and is then used in generated lemmas.

**Limitations.** The above example demonstrates our method’s potential advantages, but also raises a question regarding its generality: can the pattern database be sufficiently extensive, i.e., apply to a sufficient range of programs, so as to make our approach worthwhile? Indeed, if one needed to “teach” the solver new patterns for every new input program, the method would boil down to a manual compositional proof.

We believe that the answer to this question is affirmative: our findings show that even a small set of patterns included within the \( TS \) solver may already apply to broad classes of interesting programs. We demonstrate two such cases, periodic programs and programs with arrays, in Sections V and VI. Still, adding new patterns is not a trivial task, and so we store them in a central repository — amortizing the cost of adding additional patterns over future applications.

**The \( TS \) Solver vs. Model Checking.** In the simple example given above, our theory-aided approach could also be implemented by a more standard design: a model checker that issues queries to a black-box SMT solver. Our motivation for conducting model checking within the \( TS \) solver is in handling more elaborate examples, in which SMT theories partake in directing the state space traversal (see, e.g., Section V). While such cases can still be accommodated by a model checker that is “running the show” and an SMT solver that exposes proper callbacks, we feel that a DPLL\((T)\)-based solution is cleaner, and also more extensible and robust. By encoding the state traversal engine as a few axioms and lemma generation rules, and by having the pattern matching mechanism likewise generate lemmas, the complexity of integrating and synchronizing the two is automatically and seamlessly handled by CVC4’s DPLL\((T)\) core — simplifying the implementation of the \( TS \) solver. Further, this enables the \( TS \) solver to be plugged into any other SMT solver that adheres to the DPLL\((T)\) framework.

**V. Verifying Periodic Programs**

In this section, we discuss the theory-aided verification of periodic programs [25] — a class of single processor scheduling problems that have been widely studied over the last decades. A periodic program consists of a finite set of tasks \( T_1, \ldots, T_n \), which are processes that repeatedly need to be scheduled for execution on a single processor. Each task \( T_i \) is characterized by its period time \( P_i \) and an execution time \( C_i \) (for simplicity, we ignore here other parameters such as relative deadlines and initial offsets). From task \( T_i \)'s point of view, the execution of the program is divided into time cycles of length \( P_i \); each, and in each such cycle the task must be allotted \( C_i \) time slots on the processor. The least common multiple of the tasks’ period times is called the program’s hyper-period. Tasks may have priorities: a task with a higher priority will preempt another if both need to be scheduled at a specific point in time. A periodic program is said to be schedulable if there exists a task scheduling in which no deadlines are violated. See Section C of the supplementary material [23] for an example.

Here, we study the verification of safety properties in periodic programs: we assume that the input program is schedulable, and check whether it can violate a given property. This is typically done by transforming the periodic program into an equivalent sequential program and then verifying it using standard model checking [7]. Our approach is similar, but we seek to leverage the program’s special structure in order to explore only a portion of its state space.

In RWB, periodic programs may be programmed by expressing each task as a thread that requests an event whenever the task needs to be scheduled [15]. Priorities are expressed using blocking: a thread (task) may block events belonging to other threads with lesser priorities. Fig. 5 illustrates the structure of task threads and describes their pattern matcher.

Whenever all input threads are identified as tasks, the pattern recognizer reports that the program is periodic. This causes the pattern’s lemma generation function to be repeatedly invoked during state space traversal, so that it may generate lemmas aimed at curtailing the search space. For this pur-
Figure 5: An \textit{RWB} implementation of a task thread with period time \(P = 5\) and execution time \(C = 2\). The thread’s underlying transition system can be regarded as a \((C' + 1) \times P\) matrix, where the columns represent the time passed since the beginning of the period and the rows represent the number of times the task has been scheduled so far. Green edges in the figure represent the task being successfully scheduled (i.e., its requested event was triggered), and red edges represent the task not being scheduled (an event requested by some other task was triggered). Thus, with every time unit the state moves to the right, and if the task was scheduled it also moves one row down. If the task’s deadline is violated, it enters a deadlock state (the rightmost state in the figure). The task pattern matcher traverses the state graph of each input thread and checks whether it has these structural properties. If so, it also extracts the task’s \(P\) and \(C\) parameters and its sequence of requested events (not illustrated). If blocking is used to prioritize tasks, the matcher also extracts the prioritization hierarchy.

pose, we extend the signature of \(TS\) to include a sort \(\mathbb{Z}^{+}\) for non-negative integers, and the predicate deadlock\(_{Q}\) : \(S_{Q} \times \mathbb{Z}^{+}\). Intuitively, deadlock\(_{Q}(s, t)\) indicates that a deadlock state in \(s\) is reachable in \(t\) steps from an initial state. Further, we extend \(TS\) to support backward reachability analysis, in addition to the forward reachability analysis afforded by the \textit{safe-state} predicate. To this end, we add the reachable\(_{Q}\) : \(S_{Q} \times Q\) predicate, with the following semantics:

\[
\forall s, q: Q. \text{reachable}(s, q) \iff I(s, q) \lor \exists q': S_{Q}, e: E. (Tr(s, q', e, q) \land R(s, q', e) \land \lnot B(s, q', e) \land \text{reachable}(s, q'))
\]

Intuitively, a state is reachable if it is initial or has a reachable predecessor. For more details, see Section B of the supplementary material [23].

The lemmas generated by the pattern matcher assert that there must be a time \(t\) within the hyper-period in which a violation occurs. They also limit the possible values of \(t\) based on the information gathered about the individual tasks. Specifically, the pattern generator makes the lemma:

\[
\Psi_{t} \land \Phi \implies \exists s: \mathbb{Z}^{+}. \text{deadlock}(s, t) \land \Psi_{t}
\]

where \(\Psi_{t}\) describes constraints on \(t\) that are deduced from the structure of the task threads. If the arithmetic solver finds a solution \(t_{0}\) for \(\Psi_{t}\), it assigns it to \(t\), and the \(TS\) solver then translates it, by analyzing the task threads’ possible locations in time \(t\), into candidate reachable bad states \(q_{1}, \ldots, q_{t}\):

\[
\forall s, q: Q. \text{reachable}(s, q) \implies \text{reachable}(s, q_{1}, \ldots, q_{t})
\]

\(TS\) then performs backward reachability checks on candidates \(q_{1}, \ldots, q_{t}\). If a path to an initial state is found, the system is unsafe and we are done. Otherwise, the contradiction forces the arithmetic solver to propose another solution \(t = t_{1}\), which corresponds to additional candidate bad states. The process is repeated until the system is proven unsafe, or until all possible solutions are exhausted. Other bad states, which do not correspond to any of the proposed values of \(t\), are guaranteed to be unreachable and are ignored.

In order to generate the constraints in \(\Psi_{t}\), the pattern matcher identifies tasks participating in the violation: these are the threads whose requested events are part of a violating sequence. Then, it uses information about these threads, and about threads with higher priority, to put constraints on \(t\).

We demonstrate this on a schedulable periodic program with 4 tasks: task \(T_{1}\) with parameters \(P_{1} = 5, C_{1} = 1\); \(T_{2}\) with \(P_{2} = 6, C_{2} = 1\); \(T_{3}\) with \(P_{3} = 9, C_{3} = 3\); and task \(T_{4}\) with parameters \(P_{4} = 11, C_{4} = 2\). Task 1 has the highest priority, task 2 has the second highest priority, and tasks 3 and 4 both share the lowest priority. The safety property in question is that it is impossible for task \(T_{4}\) to be scheduled for three consecutive time slots. Here, direct model checking requires visiting 55000 states in the composite program.

By intersecting the violating event sequence with the events requested by each thread, the pattern matcher determines that \(T_{4}\) is the only participating task. By the information extracted regarding task priorities, it deduces that tasks \(T_{1}\) and \(T_{2}\) supersede it. Then, it generates the \(\Psi_{t}\) constraint as follows. One conjunct in \(\Psi_{t}\) is \(0 \leq t \leq 990\), as the hyper-period is \(lcm(5, 6, 9, 11) = 990\). Another conjunct is \(((t \geq 3 \text{ (mod } 5)) \land (t \geq 3 \text{ (mod } 6))\): if it did not hold, \(T_{1}\) or \(T_{2}\) would preempt \(T_{4}\), preventing it from being scheduled 3 consecutive times. Yet another conjunct is \((t \leq 1 \text{ (mod } 11))\); it holds because in order for \(T_{4}\) to be scheduled 3 consecutive times (with execution time \(C_{4} = 2\), a fresh period must start at time \(t\) or \(t-1\). A few additional conjuncts are omitted. The complete lemma reduces the number of possible values for \(t\) from 990 to just 15, and the query as a whole entails exploring only 700 states out of 55000 reachable states in order to prove the system’s safety.

VI. VERIFYING PROGRAMS WITH SHARED ARRAYS

Next we demonstrate the theory-aided verification of programs with shared arrays — a widespread construct in concurrent programming. In the \textit{RWB} model, a shared \(m\)-ary array with \(n\) cells may be implemented using \(n\) b-threads, each of size \(m\). Each thread represents a single array cell and has a clique-like structure, where each state \(s_{i}\) is associated with a write event \(w_{i}\) and a read event \(r_{i}\). Intuitively, each state \(s_{i}\) corresponds to a value \(v_{i}\) that is stored in the array cell. Whenever event \(w_{i}\) is triggered, the thread moves to state \(s_{i+1}\); and whenever not in state \(s_{i}\), the thread blocks \(r_{i}\). Thus, other threads can request \(r_{i}\) in order to check if the thread is in state \(s_{i}\) (i.e., to check if the array cell has value \(v_{i}\)). See Fig. 6 for an illustration. Note that this implementation is only needed for shared arrays; internally, threads may use any construct available in the underlying programming language.

Figure 6: An \textit{RWB} implementation of a binary array with \(n\) cells. Each cell is represented by a thread with two states, signifying the stored value in that cell: 0 or 1. Each thread/cell is associated with two write events, for 0 and 1; when they occur, the thread changes states to indicate the new stored value. Other threads in the program may read from a cell by requesting the two read events associated with it, one for 0 and one for 1; the read event that does not match the value in the cell will be blocked by the cell thread, and so only the “correct” read event may be triggered.

The \(TS\) solver has a pattern matcher that looks for threads that match this array cell pattern. If an array is found, the pattern matcher checks whether deadlocks are possible only in certain array configurations (e.g., when certain array cells...
hold certain values; an example appears later in this section). If such constraints are found, it generates a lemma that conditions the system’s unsafety on the array threads reaching an unsafe configuration.

We demonstrate with an example. Observe a program with a shared array of size \( n \) and an initial state \( q_0 \). The array pattern matcher creates an array expression \( arr_{q_0} \) whose value at each index \( i \) is set to some fresh constant \( c_i \). This expression is used to represent the value of the array in various states of the program. The matcher also creates a target array, \( arr_{\text{target}} \), and asserts constraints on \( arr_{\text{target}} \) signifying the state that the array has to be in for a violation to occur. Then, it generates the lemma \( \Phi \land \Phi \implies (arr_{q_0} = arr_{\text{target}}) \).

The bulk of the work is then performed as \( TS \) traverses the state space. Whenever a new state \( q \) is visited, the pattern matcher analyzes the threads (each of them separately), looking for array entries that have become fixed. This can be determined, e.g., when additional write events to a cell are never requested or are always blocked. Suppose that it is discovered that the first cell’s value has been fixed to \( c_0 \); then the lemma \( \Phi \land \Phi \land \neg \text{safe}_{\text{state}}(s,q) \implies (c_0 = c_0) \) is generated. If this is consistent with the earlier assertion \( arr_{q_0} = arr_{\text{target}} \), the solver continues traversing the successors of \( q \); otherwise, the array theory solver will raise a conflict, resulting in \( q \)’s successor states not being traversed.

A more detailed example and an evaluation of applying the shared array pattern to a web-server application appears in Section VII. An additional detailed example regarding the verification of an \( RWB \) application for playing Tic-Tac-Toe appears in Section D of the supplementary material [23].

VII. EXPERIMENTAL RESULTS

We evaluated our proof-of-concept tool, implemented as an extension to CVC4, by comparing it to BPMC — a symbolic model checker specifically designed for \( RWB \) programs [19], [22] (the tool and experiments are available online [23]). Our tool uses a portfolio approach: if the input program does not match any of the known patterns, the tool simply invokes BPMC (or any other model checker, for that matter). The decision of whether or not to invoke BPMC is made within seconds, rendering the performance of both tools effectively the same in these cases. Hence, for the remainder of this section we focus on inputs in which a pattern did apply and theory-aided model checking was indeed attempted.

We first compared the tools using a benchmark suite of over 120 hand-crafted \( RWB \) programs — some benchmark, and some containing shared arrays. The benchmarks’ sizes ranged from a few hundred to over 10 million reachable states, and contained both SAT and UNSAT instances. The results are depicted and discussed in Fig. 7.

Next, we set out to test our tool’s applicability to a large, real-world system by using it to verify safety properties on a web-server (implementing TCP and HTTP stacks) written in BPC [16]. We were very curious to see whether our pattern recognition mechanism would pick up any matching threads.

As it turns out, the shared array pattern proved useful in verifying this application. Per the TCP protocol, the web-server only accepts TCP push segments on active connections. Slightly simplified, a connection to a client is active if the client sent a syn segment but not a fin segment. This functionality is implemented using blocking: for every connection, a dedicated thread, named \( EnsureActiveConnection \), blocks push events while the connection is inactive. This blocking is removed when a syn segment is received, and is restored when a fin segment is received. Thus, the \( EnsureActiveConnection \) threads were picked up as shared array cells by our tool: they each had two states, labeled active and inactive, with respective read events push and reject and write events syn and fin. Interestingly, the programmers of the web-server did not seem to have had this design pattern in mind [16].

We tested 10 safety properties on the web-server (see Fig. 8). These properties included the proper rejection of messages on inactive connections, proper usage of allotted sequence numbers for outgoing segments, and the detection and blocking of unstable clients, who quickly and repeatedly opened and closed connections. The theory-aided approach did better on 7 of 10 instances (4 SATs and 3 UNSATs), demonstrating an average speedup of 16% over all instances. BPMC did better on 2 SAT and 1 UNSAT instances, where the property in question and the discovered patterns were disparate (e.g., properties involving proper usage of sequence numbers, that had nothing to do with the \( EnsureActiveConnection \) threads).

These initial results are encouraging. We conclude that (i) the theory-aided approach is viable, in the sense that the stored patterns apply to real programs, sometimes significantly reducing verification times; and (ii) that performance may be further improved by enhancing the portfolio approach; i.e., if we were able to more accurately characterize cases in which, despite matching a stored pattern, a thread does not affect the property in question, we could delegate those cases to BPMC and achieve faster running times. This is left for future work.

VIII. RELATED WORK AND DISCUSSION

In this work, we proposed a framework for the automated compositional verification of concurrent software. Our technique was based on casting the model checking problem into the DPLL(T) framework used by the CVC4 SMT solver, and then utilizing other theory solvers to prune the search space in order to improve performance. Other theories were able to affect the search through lemmas in their respective languages that were generated by matching the input program’s threads to presupplied patterns.

SMT solving has been used for various verification-related tasks such as lemma dispatching [8], [26], reachability analysis [4] and model-checking concurrent programs [6], [27]. Our technique shares some of these aspects, but differs in that the state exploration is driven by an SMT solver and...
in that lemmas are derived using stored patterns. A related approach for circuit verification appears in [5], where the input is analyzed to find unreachable states in advance. Our framework follows a similar spirit, but extends the technique to concurrent software and utilizes a modern SMT solver.

We evaluated our technique on two broad classes of RWB programs: periodic programs and programs with shared arrays. Specifically, we showed that the TS solver may leverage CVC4’s arithmetic and array theory solvers in order to expedite the model checking process. Others have explored SMT-based techniques for similar models; e.g., the validation of guessed invariants in Lustre programs [21]. We consider this as encouragement that applying SMT-based techniques to synchronous, discrete event models may prove fruitful, and intend to extend our technique to Lustre as well.

We find our initial results encouraging, and plan to continue extending our pattern database. One direction that we are presently pursuing is the addition of a new pattern matcher that leverages CVC4’s string theory solver [24], by translating constraints imposed by certain types of input threads into regular expressions. Indeed, a prototype implementation we have created shows interesting potential.
