Stochastic Control With Affine Dynamics and Extended Quadratic Costs

Shane Barratt and Stephen Boyd, Fellow, IEEE

Abstract—An extended quadratic function is a quadratic function plus the indicator function of an affine set, i.e., a quadratic function with embedded linear equality constraints. In this article, we show that, under some technical conditions, random convex extended quadratic functions are closed under addition, composition with an affine function, expectation, and partial minimization, i.e., minimizing over some of its arguments. These properties imply that dynamic programming can be tractably carried out for stochastic control problems with random affine dynamics and extended quadratic cost functions. While the equations for the dynamic programming iterations are much more complicated than for traditional linear quadratic control, they are well suited to an object-oriented implementation, which we describe. We also describe a number of known and new applications.

Index Terms—Convex optimization, dynamic programming (DP), stochastic control.

I. INTRODUCTION

Many practical problems can be modeled as stochastic control problems. Dynamic programming (DP), pioneered by Bellman in the 1950s [1], provides a solution method, at least in principle [2]. DP relies on the cost-to-go, value, or Bellman function (on the state space), which is computed by an iteration involving a few operations such as addition, expectation over random variables, and minimization over the allowed actions or controls. The cost-to-go function can be tractably represented, and these operations can be carried out tractably in only a few special settings.

1) Finite state and control spaces: In this case, the cost-to-go function and the control policy can be explicitly represented by lookup tables.

2) Vector-valued states and controls, linear dynamics, and convex quadratic cost: This is the famous linear quadratic control or regulator (LQR) problem. In this case, the cost-to-go function is a convex quadratic form, represented by a matrix, and the control policy is linear, represented by a gain matrix [3].

Despite the special forms of these two cases, they are very widely applied. There are a few other very specialized cases where DP is tractable, such as the optimal consumption problem [4].

For cases where exact DP is intractable, many methods have been developed to approximately solve the problem, such as approximate DP, reinforcement learning, and many others. These methods can be very effective in practice, depending on the approximations or algorithms used, which can vary across applications. There is a vast literature on these methods; see, e.g., [5]–[12], and the many references in them.

Our focus in this article is to identify a class of stochastic control problems that, like the two special cases mentioned above, can be solved exactly. Our class is a generalization of the classic LQR problem. The class of problems, which we formally describe in the following section, has a state with a vector-valued and finite part (which we call the mode), a vector-valued control, random mode-dependent affine dynamics, random mode-dependent extended quadratic cost, and state/control-independent Markov chain dynamics for the mode. Extended quadratic functions, which we define formally in the section, are quadratic functions that include linear and constant terms, as well as implicit linear equality constraints. Many special cases of our general problem class have been noted and solved in the literature, e.g., so-called jump-linear quadratic control [13], [14] and LQR with random dynamics [15]. We unify these problems under one common problem description and solution method; in addition, our class includes problems that, to the best of authors’ knowledge, have not been addressed in the literature.

While DP for our class of problems can be carried out exactly (modulo how expectation is carried out), the equations that characterize the cost-to-go function and the policies are not simple, and in particular, are far more complex than those for LQR, which are well known. Our approach is to develop an object-oriented solution method. To do this, we identify the key functions and methods that must be carried out, and describe how to implement them; DP simply uses these methods, without expanding the equations and formulas. This approach has several advantages. First, it can be immediately implemented (and indeed, has been). Second, it focuses on the critical ideas without getting bogged down in complicated equations, as the traditional approach would. Third, its generality and compositional form allows it to apply to a wide variety of problems; in particular,
components can be rearranged to solve other problems not described here.

A. Related Work

Stochastic control has applications in a wide variety of areas, including supply chain optimization [16], [17], advertising [18], finance [4], [19], dynamic resource allocation [20], [21], and traditional automatic control [22]. DP is by far the most commonly employed solution method for stochastic control problems. DP was pioneered by Bellman in the 1950s [1]; for a modern treatment and its applications to stochastic control see the textbooks by Bertsekas [2], [23], [24] and the many references in them.

The linear-quadratic Gaussian (LQG) stochastic control problem traces back to Kalman in the late 1950s [25] and was studied heavily throughout the 1960s (see [26] and its many references). Since then, many tractable extensions of LQG have been proposed. Two of the most notable extensions that have been formulated (and solved) are jump linear quadratic control (jump LQR) and random LQR, which we now describe.

One special case of the class of problems described in this article is jump LQR, where the dynamics are linear but suddenly change according to a fully observable Markov chain process. The optimal policy for this problem in continuous time was first identified by Krasovskii and Lidsky in 1961 [14] and Florentin [13], and discovered independently by Sworder in 1969 [27]. The problem was then solved in discrete time [28], where the authors found that the cost-to-go functions are quadratic for each mode and that the optimal policy is linear for each mode. These results were extended to the infinite-horizon case by Chizeck et al. [29] and to have equality constraints in the cost by Costa et al. [30]. (See [31] and the references therein for a comprehensive overview of jump LQR.) Jump LQR was applied early on to robust control system design [32], later to reliable placement of control systems components [33], and also to distributed control with random delays [34].

The other important special case is random LQR. In random LQR, the goal is to control a system that has random affine dynamics and quadratic stage cost. This problem was first identified and solved by Drenick and Shaw in 1964 [15] and then in continuous time by Wonham in 1970 [35]. For a more modern treatment in discrete time, see the paragraph “Random System Matrices” in [2, pg. 123–124]. The random LQR problem was extended to have (jointly) random quadratic stage cost and equality constraints in [36], and has been applied to finance in [37]–[39]. All of these works have (somewhat independently) derived that the cost-to-go functions are quadratic and that the optimal policies are an affine function of the state.

B. Contributions

To the best of the author’s knowledge, no one has combined the jump and random LQR problems into a single general stochastic control problem class and identified the form of the solution. This article can be viewed as a unification of these two problem classes, while maintaining the familiar tractability of LQR. We also present a number of extensions and variations of the problem class, which to the best of authors’ knowledge, have not appeared in the literature. In addition, this article provides an object-oriented implementation of extended quadratic functions, which powers the solution methods we present for the problem class. The code and all presented examples are freely available online.¹

II. PROBLEM STATEMENT

We consider discrete-time dynamical systems, with dynamics described by

\[ \begin{align*}
  x_{t+1} & = f_t^{s_t}(x_t, u_t, w_t), & t = 0, 1, \ldots \\
  s_{t+1} & = i \text{ with probability } \Pi_{t,ij} \text{ if } s_t = j, & t = 0, 1, \ldots 
\end{align*} \]

where \( t \) indexes time. Here, \( x_t \in \mathbb{R}^n \) (the set of real \( n \)-vectors) is the state of the system at time \( t \), \( s_t \in \{1, \ldots, K\} \) is the mode of the system at time \( t \), \( u_t \in \mathbb{R}^m \) is the control or input to the system at time \( t \), \( w_t \in \mathcal{W}_t \) is a random variable corresponding to the disturbance at time \( t \), \( f_t : \mathbb{R}^n \times \mathbb{R}^m \times \mathcal{W}_t \to \mathbb{R}^n \) are the state transition functions at time \( t \) when the system is in mode \( s_t \) and \( \Pi_t \) is the mode switching probability matrix at time \( t \).

In this article, we consider state transition functions that are affine in \( x \) and \( u \), i.e.,

\[ f_t(x, u, w) = A_t^s(x)x + B_t^s(u)u + c_t^s(w), \quad t = 0, 1, \ldots \]

where \( A_t^s : \mathcal{W}_t \to \mathbb{R}^{n \times n} \) (the set of real \( n \times n \) matrices) is the dynamics matrix at time \( t \) when the system is in mode \( s_t \), \( B_t^s : \mathcal{W}_t \to \mathbb{R}^{n \times m} \) is the input matrix at time \( t \) when the system is in mode \( s_t \), and \( c_t^s : \mathcal{W}_t \to \mathbb{R}^n \) is the offset at time \( t \) when the system is in mode \( s_t \).

Because the disturbances \( w_t \) and the modes \( s_t \) are random variables, this makes \( x_t \) and \( u_t \) random variables. We assume that \( w_t \) is independent of \( x_t, u_t, s_t \), and \( w_t' \) for \( t' \neq t \). We often have that \( f_t, \Pi_t, \) and the distribution of \( w_t \) do not depend on \( t \), in which case the dynamics are said to be time-invariant. In some applications, the dynamics matrix, the input matrix, or the offset do not depend on \( w_t \), i.e., they are deterministic.

At time \( t \), we choose \( u_t \) given knowledge of the previous states \( x_0, \ldots, x_t \) and modes \( s_0, \ldots, s_t \), but no knowledge of the disturbance \( w_t \). For the problem, we consider it can be shown that there is an optimal policy that only depends on the current state and mode [2], i.e., we can express an optimal policy as

\[ u_t = \phi_t^{s_t}(x_t), \quad t = 0, 1, \ldots \]

where \( \phi_t^{s_t} : \mathbb{R}^n \to \mathbb{R}^m \) is called the policy at time \( t \) for mode \( s_t \).

When we refer to \( \phi_t \) without the superscript, we are referring to the collection of policies at that time step. If \( \phi_t \) do not depend on \( t \), then the policy is said to be time-invariant and is denoted \( \phi \).

A. Finite-Horizon Problem

In the finite-horizon problem, our objective is to find a sequence of policies \( \phi_0, \ldots, \phi_{T-1} \) that minimize the expected cost over a finite time horizon, given by

\[ E \left[ \sum_{t=0}^{T-1} g_t^{s_t}(x_t, \phi_t^{s_t}(x_t), w_t) + g_T^{s_T}(x_T) \right] \]

¹https://github.com/cvxgrp/extquadraccontrol
subject to the dynamics (1), where $T$ is the horizon length, the expectation is over $w_0, \ldots, w_{T-1}$ and $s_0, \ldots, s_{T-1}$, and $g^t_s: \mathbb{R}^n \times \mathbb{R}^m \times \mathcal{W}_t \to \mathbb{R} \cup \{+\infty\}$ is the stage cost function for time $t$ when the system is in mode $s$, and $g^T_s: \mathbb{R}^n \to \mathbb{R}$ is the final stage cost function.

In this article, we consider stage cost functions of the form

$$g^t_s(x, u, w) = \frac{1}{2} \begin{bmatrix} x^T \\ u^T \\ 1 \end{bmatrix} G^t_s(w) \begin{bmatrix} x \\ u \\ 1 \end{bmatrix} + \begin{cases} 0 & F^t_s x + H^t_s u + h^t_s = 0 \\ +\infty & \text{otherwise} \end{cases}$$

where $G^t_s : \mathcal{W}_t \to \mathbb{S}^{n+m+1}$ ($\mathbb{S}^n$ denotes the set of real symmetric $n \times n$ matrices), $F^t_s \in \mathbb{R}^{m \times n}$, $H^t_s \in \mathbb{R}^{p \times m}$, and $h^t_s \in \mathbb{R}^p$. Stage cost functions that have this form are extended quadratic functions of $x$ and $u$, which are quadratic functions with embedded linear equality constraints, discussed in much greater detail in Section III. Including the embedded linear equality constraints is equivalent to a constraint on the system that at time $t$, if $s_t = s$, the system should satisfy $F^t_s x_t + H^t_s u_t + h^t_s = 0$. We consider a final stage cost function of the form

$$g^T_s(x) = \frac{1}{2} \begin{bmatrix} x^T \\ 1 \end{bmatrix} G^T_s \begin{bmatrix} x \\ 1 \end{bmatrix} + \begin{cases} 0 & F^T_s x + h^T_s = 0 \\ +\infty & \text{otherwise} \end{cases}$$

where $G^T_s \in \mathbb{S}^{n+1}$, which is an extended quadratic function of $x$.

B. Infinite-Horizon Problem

In the infinite-horizon problem, we assume that the dynamics and cost are time-invariant. Our goal is to find a time-invariant policy $\phi$ that minimizes the expected cost over an infinite-time horizon, given by

$$\lim_{T \to \infty} \mathbb{E}[\sum_{t=0}^{T} \gamma^t g^{s_t}(x_t, \phi^{s_t}(x_t), w_t)]$$

subject to the dynamics (1), where $\gamma \in (0, 1]$ is the discount factor, the expectation is taken over $w_t$ and $s_t$, and $g^s : \mathbb{R}^{n} \times \mathbb{R}^{m} \times \mathcal{W}_t \to \mathbb{R} \cup \{+\infty\}$ is the stage cost function indexed by $s$. We consider stage cost functions that are extended quadratic functions of $x$ and $u$. One can recover the undiscounted infinite-horizon problem by letting $\gamma = 1$.

We call the abovementioned problems extended quadratic control problems.

C. Problem Data Representation

Throughout this article, we assume that we have, at a bare minimum, access to an oracle that provides independent samples of the random quantities

$$A^t_s(w), B^t_s(w), c^t_s(w), G^t_s(w)$$

for all $t, s$. The samples can be given in batch, e.g., a sample of $N$ dynamics matrices $A^t_s$ for time $t$ would result in an $N \times K \times n \times n$ matrix. We will see later that, in some cases (namely, when the cost-to-go function is a non-extended quadratic function), additional knowledge of the distributions (in particular, their first and second moments) can be used to derive analytic expressions for expectations of quadratic functions.

In addition, we assume that we have access to the (deterministic) quantities

$$\Pi_t, F^t_s, H^t_s, G^T_s, F^T_s, h^T_s$$

for all $t, s$. These could be represented by matrices, e.g., $\Pi_t$ for time $t$ would be a $K \times K$ matrix.

D. Pathologies

There are several pathologies that can (and often do) occur in our formulation, depending on the exact problem data and distributions.

1) Infinite cost: This happens if, e.g., the equality constraints are impossible to satisfy or the expectation is $+\infty$ for all policies.

2) Cost that is unbounded below: There exist policies that achieve arbitrarily low cost.

3) Cost that is undefined: The expectations in (2) or (3) do not exist.

Many of these pathologies are discussed in great detail in [24] and [23].

In this article, we do not focus on analyzing when these pathologies occur in the class of problems that we consider, but rather on the practical application and implementation of these methods. Also, in well posed practical problems, these pathologies rarely occur. Nevertheless, the algorithms that we describe are capable of catching many of these pathologies and reporting the nature of the pathology.

E. Results

In the absence of the pathologies described earlier, we show in this article that there is an optimal policy in the finite-horizon problem that is an affine function of $x$, meaning the policy has the form

$$\phi^s_t(x) = K^t_s x + k^t_s$$

where $K^t_s \in \mathbb{R}^{m \times n}$ is the input gain matrix and $k^t_s \in \mathbb{R}^m$ is the input offset matrix. For the infinite-horizon problem, there is a policy that is a time-invariant affine function of $x$. Also, the cost-to-go functions are extended quadratic functions of $x$ for each mode $s$.

When $k^t_s \in \mathbb{R}(K^t_s)$ (the range of the matrix $K^t_s$), we can express the policy in the following more interpretable form:

$$\phi^s_t(x) = K^t_s(x - (x^*)^t_s)$$

where $(x^*)^t_s = -(K^t_s)^{-1} k^t_s$. Here, $(K^t_s)^{-1}$ denotes the Moore–Penrose pseudoinverse. This has a convenient interpretation; to select $u_t$, we calculate the difference between $x$ and our desired state $(x^*)^t_s$ and then multiply that difference by the input gain matrix. We can then interpret the policy as regulating the state toward the desired state.
III. Extended Quadratic Functions

In this section, we describe extended quadratic functions, which are quadratic functions with embedded linear equality constraints. We explain how to verify attributes like convexity, how they can be combined or precomposed with an affine function, and how to carry out partial minimization, where we minimize over a subset of the variables.

An extended quadratic function \( f : \mathbb{R}^n \to \mathbb{R} \cup \{+\infty\} \) has the form

\[
f(x) = \frac{1}{2} x^T \begin{bmatrix} P & q \\ q^T & r \end{bmatrix} x + \mathcal{I}_{F,g}(x)
\]

where \( P \in \mathbb{S}^n \), \( q, r \in \mathbb{R}^n \), and \( \mathcal{I}_{F,g} \) is the indicator function of the linear equality constraint \( Fx + g = 0 \)

\[
\mathcal{I}_{F,g}(x) = \begin{cases} 0 & Fx + g = 0 \\ +\infty & \text{otherwise} \end{cases}
\]

as the quadratic part of \( f \), and we refer to \( \mathcal{I}_{F,g}(x) \) as the embedded equality constraints in \( f \). We refer to \( n \) as the dimension of (the argument of) \( f \). We allow \( p = 0 \), i.e., the case when there are no embedded equality constraints in \( f \). In this case, we refer to \( f \) as a (nonextended) quadratic function.

A. Special Cases and Attributes of Extended Quadratic Functions

An extended quadratic function \( f \) is proper [40] if there exists \( x \) with \( f(x) < +\infty \), i.e., the embedded equality constraints are feasible. An extended quadratic function \( f \) is an extended quadratic form if \( q = 0 \), \( r = 0 \), and \( g = 0 \) (or \( p = 0 \)); in this case, it is homogeneous of degree two. If in addition there are no equality constraints, i.e., \( q = 0 \), \( r = 0 \), and \( p = 0 \), \( f \) is a quadratic form. It is extended affine if \( P = 0 \), and affine if in addition there are no constraints. An extended quadratic function \( f \) is extended constant if \( P = 0 \) and \( q = 0 \).

B. Free Parameter Representation of Equality Constraints

The representation of the embedded equality constraints by \( F \) and \( g \) is evidently not unique. For example, if \( \bar{F} \in \mathbb{R}^{p \times p} \) is invertible, \( \bar{F} = TF \) and \( \bar{g} = Tg \) give another representation of the same constraints, i.e., \( \mathcal{I}_{F,g} = \mathcal{I}_{\bar{F},\bar{g}} \). To resolve this nonuniqueness, and for other tasks as well, it will be convenient to express the equality constraints in free parameter form, parametrized by \( x_0 \in \mathbb{R}^n \) and \( V_2 \in \mathbb{R}^{n \times n} \), with \( l = n - \text{rank}(F) \)

\[
\{ x \mid Fx + g = 0 \} = \{ V_{2z} + x_0 \mid z \in \mathbb{R}^l \}.
\]

Here, \( x_0 \) is any particular solution of \( Fx + g = 0 \), and \( \mathcal{R}(V_2) = \mathcal{N}(F) \) (i.e., the nullspace of \( F \)). Without loss of generality, we can assume that \( V_2^T V_2 = I \). (We will explain the subscript in \( V_2 \) shortly.)

We can determine whether the constraints are feasible, and if so, find such a free parameter representation using the (full) singular value decomposition (SVD) of \( F \)

\[
F = \begin{bmatrix} U_1 & U_2 \end{bmatrix} \begin{bmatrix} \Sigma & 0 \\ 0 & 0 \end{bmatrix} \begin{bmatrix} V_1 & V_2 \end{bmatrix}^T
\]

where \( \Sigma \in \mathbb{R}^{s \times s} \) contains the positive singular values of \( F \) with \( s = \text{rank}(F) \). Then, \( Fx + g \) is feasible if and only if \( U_2^T g = 0 \), and we can take \( x_0 = -V_1 \Sigma^{-1} U_1^T g = -F^\dagger g \), where \( F^\dagger \) is the (Moore–Penrose) pseudo-inverse of \( F \). We can take \( V_2 \) as the matrix in our free parameter representation (5). Finally, we note that we can replace the representation \( F \) and \( g \) with \( \bar{F} = V_1^T F \)

\[
\text{and } \bar{g} = \Sigma^{-1} U_1^T g.
\]

In this case, \( \bar{F} \) satisfies \( \bar{F} \bar{F}^T = I \), i.e., its rows are orthonormal. We refer to a representation of equality constraints with \( \bar{F} \bar{F}^T = I \) (i.e., with orthonormal rows) as in reduced form. Reducing an extended quadratic corresponds to converting its equality constraints to reduced form, which can be done via the SVD as described earlier.

C. Equality of Constraints

Using the decomposition mentioned above, we can check whether two descriptions of equality constraints (possibly of different dimensions \( p \) and \( \tilde{p} \)) are equal, i.e., \( \mathcal{I}_{F,g} = \mathcal{I}_{\tilde{F},\tilde{g}} \). Let \( x_0, V_1, V_2, \tilde{x}_0, \tilde{V}_1, \tilde{V}_2 \) correspond to the free parameter representation above for \( f \) and \( \tilde{f} \), respectively. Clearly we must have \( \text{rank}(F) = \text{rank}(\tilde{F}) \), and in addition

\[
V_1^T \tilde{V}_2 = 0, \quad V_1^T \tilde{x}_0 + g = 0, \quad \tilde{V}_1^T V_2 = 0, \quad \tilde{V}_1^T \tilde{x}_0 + \tilde{g} = 0.
\]

D. Equality of Extended Quadratics

Two extended quadratics are equal, i.e., \( f(x) = \tilde{f}(x) \) for all \( x \in \mathbb{R}^n \), if and only if \( \mathcal{I}_{F,g} = \mathcal{I}_{\tilde{F},\tilde{g}} \) (discussed earlier), and in addition

\[
f(x_0 + V_2 z) = \tilde{f}(x_0 + V_2 z) \quad \forall z \in \mathbb{R}^l.
\]

Because \( \mathcal{I}_{F,g} = \mathcal{I}_{\tilde{F},\tilde{g}} \), we can use the same free parameter representation.

Convexity: Let \( f \) be an extended quadratic function with free parameter representation \( x_0, V_2 \), as described earlier. We have that \( f \) is convex if and only if \( V_2^T PV_2 \geq 0 \) (\( A \geq 0 \) means the symmetric matrix \( A \) is positive semidefinite). It is strictly convex if and only if \( V_2^T PV_2 > 0 \) (\( A > 0 \) means \( A \) is positive definite).

E. Nonnegativity

An extended quadratic is nonnegative if and only if

\[
\begin{bmatrix} V_2 & x_0 \end{bmatrix}^T \begin{bmatrix} P & q \\ q^T & r \end{bmatrix} \begin{bmatrix} V_2 & x_0 \end{bmatrix} \geq 0.
\]

F. Sum

The sum of two extended quadratics of the same dimension, is also an extended quadratic. The sum can be improper, even when \( f \) and \( g \) are not. After adding two extended quadratics,
we can reduce the equality constraints (which also checks if the sum is proper).

G. Scalar Multiplication

We define scalar multiplication of an extended quadratic \( \alpha f \) as the extended quadratic with the same equality constraints, and quadratic part scaled by \( \alpha \)

\[
(\alpha f)(x) = \frac{1}{2} \begin{bmatrix} x \ \alpha P \ \alpha q \end{bmatrix} \begin{bmatrix} x \ \alpha q^T \ \alpha r \end{bmatrix} + I_{\mathcal{F},g}(x).
\]

If \( f \) is convex and \( \alpha \geq 0 \), \( \alpha f \) is convex. Note that when \( \alpha < 0 \), our definition of \( \alpha f \) is not the usual mathematical one, since ours takes the value \(+\infty\) when the equality constraints are violated, whereas under the usual definition, \( \alpha f \) would take the value \(-\infty\).

H. Affine Precomposition

Suppose that \( x = h(z) = Az + b \) is an affine function of \( z \), and consider \( g = f \circ h \), i.e., \( g(z) = f(Az + b) \). The function \( g \) is extended quadratic, and has the form

\[
g(x) = \frac{1}{2} \begin{bmatrix} z \ \hat{P} \ \hat{q} \end{bmatrix} \begin{bmatrix} z \ r \end{bmatrix} + I_{\mathcal{F},g}(z)
\]

where

\[
\begin{bmatrix} \hat{P} & \hat{q} \\ q^T & r \end{bmatrix} = \begin{bmatrix} A & b \\ 0 & 1 \end{bmatrix} \begin{bmatrix} P & q \\ q^T & r \end{bmatrix} \begin{bmatrix} A & b \\ 0 & 1 \end{bmatrix}.
\]

\( \hat{F} = FA \), and \( \hat{g} = Fb + g \). The equality constraints can be reduced. If \( f \) is convex, \( g \) is convex.

I. Partial Minimization

Next we consider partial minimization of an extended quadratic function, meaning we fix a subset of its variables and minimize over the other variables. There are two cases to consider as follows.

1) Strictly convex: When the function is strictly convex in the variables we are minimizing over, the function of the remaining variables is always extended quadratic.

2) Convex but not strictly convex: When the function is convex (but not strictly convex) in the variables we are minimizing over, and a technical condition holds (which always holds in the strictly convex case), the function of the remaining variables is always extended quadratic.

Suppose \( f \) is an extended quadratic function of two variables \( x \in \mathbb{R}^n \) and \( u \in \mathbb{R}^m \), i.e., it has the form

\[
f(x, u) = \frac{1}{2} \begin{bmatrix} x \ u \end{bmatrix} \begin{bmatrix} P_{xx} & P_{xu} & q_x \\ P_{ux} & P_{uu} & q_u \\ q_x^T & q_u^T & r \end{bmatrix} \begin{bmatrix} x \ u \end{bmatrix} + I_{\mathcal{F},g}(x, u)
\]

where \( F = \begin{bmatrix} F_x & F_u \end{bmatrix} \). Also suppose that \( f \) is convex in \( u \) for all \( x \). The function

\[
g(x) = \inf_u f(x, u)
\]
gives the partial minimization of \( f \) over \( u \).

Evaluating \( \inf_u f(x, u) \) is itself a convex optimization problem, and for it to be feasible, the (extended quadratic) function \( h(u) = f(x, u) \) must be proper. We have that \( h \) is proper if and only if

\[
x \in \{ x \mid F_x x + g \in \mathcal{R}(F_u) \} = \{ x \mid \hat{F} x + \hat{g} = 0 \}
\]

where \( \hat{F} = (I - F_u F_u^T) F_x \) and \( \hat{g} = (I - F_u F_u^T) g \), which is a linear equality constraint on \( x \). We can express \( g \) in the equivalent form

\[
g(x) = \inf_u f(x, u) + I_{\mathcal{F},\hat{g}}(x).
\]

We can convert the equality constraint on \( x \) above into its free parameter representation, parameterized by \( x_0 \in \mathbb{R}^n \) and \( v_2 \in \mathbb{R}^{n+l} \), i.e.,

\[
\{ x \mid \hat{F} x + \hat{g} = 0 \} = \{ V_2 z + x_0 \mid z \in \mathbb{R}^l \}.
\]

Carrying out the partial minimization to find \( g \) amounts to solving the (equality constrained quadratic) optimization problem

\[
\begin{align*}
\text{minimize} & \quad \frac{1}{2} \begin{bmatrix} u & 1 \end{bmatrix} \begin{bmatrix} P' & q' \\ q'^T & r' \end{bmatrix} \begin{bmatrix} u \\ 1 \end{bmatrix} \\
\text{subject to} & \quad F_u u + g' = 0
\end{align*}
\]

where \( P' = P_{uu} \), \( q' = P_{ux} x + q_u \), \( g' = F_x x + g \) and \( r' = x^T P_{xx} x + x^T q_x + q_u^T r + r \).

We replace \( x \) with its free parameter representation \( x_0 + V_2 z \), so that the optimization problem is guaranteed to be feasible. The KKT conditions for this problem for \( x^* \) and \( \nu^* \) to be optimal [41] are

\[
\begin{bmatrix} P_{uu} & F_u^T \\ F_u & 0 \end{bmatrix} \begin{bmatrix} u^* \\ \nu^* \end{bmatrix} = -\begin{bmatrix} q' \\ r' \end{bmatrix} = -\begin{bmatrix} P_{ux} \\ F_x \end{bmatrix} V_2 z - \begin{bmatrix} P_{ux} x_0 + q_u \\ F_x x_0 + g \end{bmatrix}.
\]

This linear system has a solution for all \( z \) if and only if

\[
\mathcal{R} \left( \begin{bmatrix} P_{uu} & F_u^T \\ F_u & 0 \end{bmatrix} \right) \supseteq \mathcal{R} \left( \begin{bmatrix} P_{ux} V_2 & P_{ux} x_0 + q_u \\ F_x V_2 & F_x x_0 + g \end{bmatrix} \right).
\]

This is the technical condition that we have been referring to. This condition is guaranteed to hold if, e.g., \( f \) is strictly convex in \( u \). If the technical condition (7) holds, then we can express a \( u^* \) as

\[
u^* = -\begin{bmatrix} I & 0 \\ 0 & 0 \end{bmatrix} \begin{bmatrix} P_{uu} & F_u^T \end{bmatrix} \begin{bmatrix} P_{ux} \\ F_x \end{bmatrix} x + \begin{bmatrix} q_u \\ g \end{bmatrix} = Ax + b
\]

where \( A \in \mathbb{R}^{n+\times m} \) and \( b \in \mathbb{R}^m \). This always satisfies the constraint \( F_x x + F_u u^* + g = 0 \).

Plugging this \( u^* \) back into (6), we find that \( g \) is an extended quadratic. (For the sake of brevity, we omitted the form of the extended quadratic.)

If (7) does not hold, or \( f \) is nonconvex in \( u \), then there is at least one \( x \) where \( g(x) = -\infty \) and \( g \) is no longer an extended
quadratic function of \( x \). We can check the technical condition (7) by noting that
\[
R(A) \supseteq R(B) \iff (I - AA^T)B = 0.
\]

**IV. DP Solution**

In this section, we use DP to show that the solutions to the problems, we consider in this article have the form (4).

**A. Finite Horizon**

The cost-to-go (or value) function \( V^*_t : \mathbb{R}^n \to \mathbb{R} \cup \{-\infty, +\infty\} \) is defined as the cost achieved by an optimal policy starting at time \( t \) from a given state and mode, or
\[
V^*_t(x) = \inf_{\phi_t} \mathbb{E} \left[ \sum_{s=t}^{T-1} g^*_s(x_s, \phi^*_s(x_s), w_s) + g^*_T(x_T, w_T) \right]
\]
subject to the dynamics (1), \( x_t = x \), and \( s_t = s \). Given a collection of functions \( V_0, V_1, \ldots, V_T \), define the Bellman operator \( \mathcal{T}_t \) applied to that collection as
\[
(\mathcal{T}_t V)^s(x) = \inf_{u, w} \mathbb{E} \left[ g^*_t(x, u, w_t) + V^{s'}(f^*_t(x, u, w_t)) \right]
\]
where \( s' = i \) with probability \( \Pi_{t,ij} \) if \( s = j \). It is well known that the cost-to-go functions \( V_0, V_1, \ldots, V_T \) satisfy the DP recursion [2], [24]
\[
V_t = \mathcal{T}_t V_{t+1}, \quad t = T - 1, \ldots, 0
\]
with \( V_T^s(x) = g^*_T(x) \).

Defining the state-action cost-to-go function \( Q^*_t : \mathbb{R}^n \times \mathbb{R}^m \to \mathbb{R} \cup \{-\infty, +\infty\} \) as
\[
Q^*_t(x, u) = \mathbb{E} \left[ g^*_t(x, u, w_t) + V^s_{t+1}(f^*_t(x, u, w_t)) \right]
\]
the optimal policies are given by
\[
\phi^*_t(x) = \arg\min_u Q^*_t(x, u).
\]

We show that, barring pathologies, the cost-to-go functions \( V^*_t \) are extended quadratic functions of \( x \) for \( t = 0, \ldots, T \). Intuitively, this is because the Bellman operator preserves the “extended quadraticity” of the cost-to-go functions.

We show this by induction. The last cost-to-go function \( V^*_T \) is extended quadratic in \( x \) by definition. Suppose, then that \( V^*_t \) is extended quadratic in \( x \). Then, \( Q^*_t \) must be extended quadratic in \( x \) and \( u \) because it is the expectation of an extended quadratic plus an extended quadratic composed with an affine function. Because \( V_t \) is equal to the partial minimization of \( Q^*_t \), an extended quadratic, \( V^*_t \) will be an extended quadratic function of \( x \). (If \( V^*_t \) is not an extended quadratic function of \( x \), then the cost is either \( +\infty \) or \( -\infty \), a pathology.) Therefore, the cost-to-go functions are extended quadratic functions of \( x \).

Because \( \phi^*_t \) is equal to the solution of partially minimizing an extended quadratic function \( Q^*_t \), it follows that there exists an optimal policy that is affine in \( x \) for each \( t, s \), and has the form in (4).

**B. Infinite Horizon**

The cost-to-go function of the infinite-horizon problem, \( V : \mathbb{R}^n \to \mathbb{R} \cup \{-\infty, +\infty\} \), is given by
\[
V^*(x) = \inf_{\phi} \mathbb{E} \left[ \sum_{t=0}^{\infty} \gamma^t g^s(x_t, \phi^s(x_t), w_t) \right]
\]
subject to the dynamics (1), \( x_0 = x \), \( s_0 = s \), where the expectation is over \( w_t \). Given a collection of functions \( H = (H^1, \ldots, H^K) \) for \( H^* : \mathbb{R}^n \to \mathbb{R} \), define the Bellman operator \( \mathcal{T} \) applied to the collection as
\[
(\mathcal{T} H)^s(x) = \inf_{u, w} \mathbb{E} \left[ g^s(x, u, w) + \gamma H^s(f^s(x, u, w)) \right]
\]
where \( s' = i \) with probability \( \Pi_{t,ij} \) if \( s = j \). It is well known that the cost-to-go function is the unique fixed point of the Bellman operator [2], [24], or
\[
V = \mathcal{T} V
\]
and that
\[
V = \lim_{k \to \infty} \mathcal{T}^k V_0
\]
for any bounded function \( V_0^s : \mathbb{R}^n \to \mathbb{R} \).

Defining the state-action cost-to-go function \( Q^* : \mathbb{R}^n \times \mathbb{R}^m \to \mathbb{R} \cup \{-\infty, +\infty\} \) as
\[
Q^*(x, u) = \mathbb{E} \left[ g^s(x, u, w) + \gamma V^{s'}(f^s(x, u, w)) \right]
\]
where \( s' = i \) with probability \( \Pi_{t,ij} \) if \( s = j \), the optimal policy is given by
\[
\phi^*_t(x) = \arg\min_u Q^*_t(x, u).
\]

We show that the cost-to-go function is an extended quadratic function of \( x \). If \( H \) is extended quadratic in \( x \), so is \( \mathcal{T} H \) by the same logic as in the finite-horizon case (barring pathologies). Starting with \( V_0(x) = 0 \), a bounded extended quadratic function, we have that \( \mathcal{T}^k V_0 \) is an extended quadratic function of \( x \) for \( k \in \mathbb{N} \). Therefore, its limit, the cost-to-function \( V \), is an extended quadratic function of \( x \).

We have that \( Q \) is extended quadratic because \( V \) is extended quadratic. Therefore, by the same logic as the finite-horizon case, there exists an optimal policy that is affine in \( x \).

**C. Avoiding Pathologies**

Pathologies are most likely to manifest when one performs partial minimization of \( Q_t \) to find \( V_t \). If \( Q_t \) is strictly convex in the variables one is minimizing over, the partial minimization will always yield an extended quadratic function of the other variables. We can enforce this by making \( g^*_t(x, u) \) convex in \( x \) and strictly convex in \( u \), but pathologies can still occur, e.g., the cost could be infinite. (This is done in LQR, where \( g(x, u) = x^T Q x + u^T R u + R + 0 \).

If \( Q_t \) is convex but not strictly convex, then in addition, the range condition (7) must hold. The best way to check this is to solve the problem and see (numerically) if the range condition holds. If it does not, then the problem is ill-posed and the cost or dynamics should be changed.
D. Linear Policies

In some problems, e.g., in classical LQR, the policies are linear functions of $x$. In this section, we come up with a sufficient condition on problems that have linear (optimal) policies.

If the dynamics are linear, and the stage cost is a convex quadratic form with homogeneous equality constraints, then the optimal policies will be linear. This is because the cost-to-go functions are quadratic forms with homogeneous equality constraints, i.e., they are of the form

$$V_t^*(x) = \frac{1}{2} \begin{bmatrix} x \end{bmatrix}^T \begin{bmatrix} P & 0 & 0 \\ 0 & r & 1 \end{bmatrix} \begin{bmatrix} x \\ 1 \end{bmatrix} + \begin{cases} 0 & F x = 0 \\ +\infty & \text{otherwise} \end{cases}.$$

This follows because quadratic forms with homogeneous equality constraints are closed under the same operations as extended quadratics. It is easy to show that the solution of partially minimizing these functions is a linear function of the other variables, meaning the policies will be linear.

V. IMPLEMENTATION

In this section, we describe how to numerically perform DP to find the cost-to-go functions, state-action cost-to-go functions, and policies, in the finite and infinite-horizon problems. One of the main difficulties in carrying out DP in the general case is representing the functions of interest. For the problems that we consider, representation is easy, since we can represent the cost-to-go functions, state-action cost-to-go functions, and policies via explicit lookup tables, indexed by time and mode, of the coefficients in the associated extended quadratic (or affine) functions.

To perform DP, all we need to do is apply the Bellman operator. The Bellman operator requires several operations on extended quadratic functions: addition, scalar multiplication (in the infinite-horizon case), affine composition, partial minimization, and expectation. The first four can be carried out using elementary linear algebra operations, as described in Section III. The remaining operation is expectation.

A. Expectation

There are the following two expectations: one over the next mode and one over the disturbance. The expectation over the next mode is easy, since there are $K$ possibilities, which we can enumerate by replacing the expectation by a weighted sum. This leaves the expectation over $w_t$.

If we only have access to a sampling oracle, we can approximate this expectation using Monte Carlo expectation, i.e., we sample $w_1, \ldots, w_N$ for some large number $N$, calculate the corresponding extended quadratic function for each $w_i$, and then average those extended quadratic functions. This is, in a way, the best that we can do given only an oracle that provides independent samples of the problem data.

When the cost-to-go function is a (nonextended) quadratic function, i.e., it has no equality constraints, we can exactly perform expectation if we know the first and second moments of the dynamics matrices and the first moment of the cost matrix, and nothing more. If, however, the cost-to-go function contains equality constraints, then we need more knowledge than just the first and second moments of the dynamics matrices, and we need to fall back to approximating the expectation using the Monte Carlo procedure explained earlier.

In our implementation, we use Monte Carlo expectation because it requires nothing more than a sampling oracle, and is easy to implement. The full version of the finite-horizon algorithm with Monte Carlo expectations is presented in Algorithm 1.

B. Infinite Horizon

To perform infinite-horizon DP, we simply call finite-horizon DP with a final stage cost function of zero, with stage cost functions multiplied by $\gamma^t$, and with the time horizon being the number of times to apply the Bellman operator. One could devise more sophisticated termination condition, e.g., terminating when $V_t$ is “close” to $V_{t+1}$, rather than applying the Bellman operator a fixed number of times. However, in practice, the cost-to-go function converges after a small number (e.g., 10–20) of iterations.

C. Python Implementation

We have developed an open-source Python library that implements Algorithm 1. The main object is ExtendQuadratic, which is initialized by supplying $P$, $q$, $r$, $F$, and $g$. One can perform arithmetic operations on ExtendedQuadratics, as well as perform affine precomposition, partial minimization, and check equality, convexity, and nonnegativity. We also provide a function that maps ExtendedQuadratics to cvxpy [42] expressions and vice versa.

The main methods are dp_finite and dp_infinite, which implement finite and infinite-horizon DP, respectively. One supplies a sampling function sample(t, N), which provides a batch sample problem data (of size $N$) for time $t$. For dp_infinite, the sample function does not take $t$ as an argument as it should be time invariant.) The functions take two additional arguments: the number of Monte Carlo samples, the time horizon (in the infinite-horizon function, this is the number of times to apply the Bellman operator), and the discount factor (in the infinite-horizon case). The method returns the cost-to-go functions $V_t^*(x)$, the state-action cost-to-go functions $Q_t^*(x, u)$, and the (optimal) policies $(K_t^*, k_t^*)$.

---

**Algorithm 1: Finite-Horizon Extended Quadratic Control.**

given $T$, $N$, $K$, $A_t^i(w)$, $B_t^i(w)$, $C_t^i(w)$, $g_t^i(w)$, $\Pi_t^i$, and independent samples $w_{1,t}^1, \ldots, w_{N,t}^T$.

Set $V_T^* = g_T^*$. 

for $t = T - 1, \ldots, 0$

1. $Q_t^i(x, u) = \frac{1}{N} \sum_{i=1}^N \sum_{s=1}^K \Pi_t^i(s)(q_t^i(x, u, w_{s,t}^i) + V_{t+1}^i(A_t^i(w_{s,t}^i)x + B_t^i(w_{s,t}^i)u + C_t^i(w_{s,t}^i)))$.

2. Partial minimization. Form $V_t^i(x) = \inf_u Q_t^i(x, u)$ and $\phi_t^i(x) = K_t^i x + k_t^i$.

end for.
D. Runtime

The finite-horizon extended quadratic control algorithm, i.e., \( T \) applications of the Bellman operator, requires approximately

\[
TK^2N \max\{1, p\} \max\{n, m\}^2
\]

operations. Our (naïve) single-threaded Python implementation applied to a random moderately sized problem with \( n = 25 \), \( m = 50 \), \( N = 100 \) (number of Monte Carlo samples), \( K = 5 \), and \( T = 25 \) Bellman operator evaluations takes about 12.8 s to calculate the optimal policies on a six-core 3.7 GHz Intel i7. The bulk of the computational effort lies in calculating the Monte Carlo expectation, which one could parallelize across multiple CPUs or GPUs to make the algorithm faster (see the message passing interface (MPI) implementation as follows).

E. MPI Implementation

We mentioned above that the algorithm could be significantly sped up with a parallel implementation. We have developed a distributed implementation using the MPI [43]. MPI is a language-independent message-passing standard designed for parallel computing, and is the dominant model in high-performance computing applications today. Although there are multiple ways to implement these algorithms in MPI, perhaps the simplest way is to parallelize the (Monte Carlo) sum over \( i \) in line 1 of Algorithm 1. If we have \( r \) processors, we can set \( N \) to a multiple of \( r \) and have each processor perform a (smaller) Monte Carlo expectation over \( N/r \) samples, and then reduce these by averaging them. This can provide significant reductions in runtime, provided \( N \) is substantially greater than the number of processors.

F. Measuring Monte Carlo Error

Our calculation of the cost-to-go functions and policies is approximate, because we use a Monte Carlo expectation instead of an exact expectation. We can measure the error in our procedure by running it multiple times with different random seeds and checking how much the cost-to-go functions and policies vary across the runs. We could also use this idea to dynamically select the number of samples used in the Monte Carlo expectations to get a solution that is within a prescribed error.

VI. APPLICATIONS

In this section, we describe several known and new applications.

A. Linear Quadratic Control or Regulator

LQR is a classical problem in control theory, first identified and solved by Kalman in the late 1950s [25]. There are many variations of LQR; in this section, we focus on the infinite-horizon LQR problem. The system has a time-invariant linear state transition function, meaning its dynamics are described by

\[
x_{t+1} = Ax_t + Bu_t + w_t, \quad t = 0, 1, \ldots
\]

where \( E(w_t) = 0 \) and \( E[w_tw_t^T] = W \), and our stage cost is a quadratic form, i.e.,

\[
g(x, u) = x^TQx + u^TRu
\]

where \( Q \succeq 0 \) and \( R > 0 \).

It is well known that the cost-to-go function is of the form \( V(z) = z^TPz \) where \( P \succeq 0 \) satisfies the algebraic Riccati equation (ARE)

\[
P = Q + A^TPA - A^TPB(R + B^TPB)^{-1}B^TPA
\]

and that the optimal policy is linear state feedback \( u_t = Kx_t \),

\[
K = -(R + B^TPB)^{-1}B^TPA.
\]

Infinite-horizon LQR (and all of its tractable variants) are instances of the problem that we describe in this article, because the dynamics are affine and the cost is a quadratic form. However, there is only one mode, the cost, dynamics, and input matrices do not depend on \( w_t \), and the stage cost is a convex quadratic form, not an extended quadratic. We know, without deriving the ARE that the cost-to-go function is a (nonextended) quadratic form and that the optimal policy is linear, and we can efficiently calculate them using the algorithms described in this article. It is worth noting that there are many other specialized (and efficient) methods of exactly solving the ARE, see, e.g., [22] and [44]. LQR serves as a good test of our numerical implementation, since we can compare the cost-to-go functions and policies that we find with specialized solvers for the ARE.

B. LQR With Random Dynamics

We can easily extend infinite-horizon LQR to incorporate random dynamics and input matrices. That is, our dynamics are described by

\[
x_{t+1} = A_t x_t + B_t u_t + c_t, t = 0, 1, \ldots
\]

where \( A_t \), \( B_t \), and \( c_t \) are (jointly) random, and we have a quadratic form stage cost. \( A_t \), \( B_t \), and \( c_t \) can have any joint distribution.

This problem was first identified and solved by Drenick and Shaw in 1964 [15] and then in continuous time by Wonham in 1970 [35]. For a more modern treatment in discrete time, see the paragraph “Random System Matrices” in [2, pg. 123–124]. The cost-to-go function in infinite-horizon LQR with random system matrices can diverge to \(+\infty\) if there is too much noise in the system; this is referred to as the uncertainty threshold principle [45], and is a great example of a pathology.

C. Numerical Example

We reproduce the results in the original paper on the uncertainty threshold principle [45]. Here, we have a one-dimensional system \( (n = m = 1) \) with dynamics described by

\[
x_{t+1} = ax_t + bu_t
\]

where \( a \sim \mathcal{N}(\bar{a}, \Sigma_{aa}) \) and \( b \sim \mathcal{N}(\bar{b}, \Sigma_{bb}) \) (where \( \mathcal{N}(\mu, \sigma) \) is the normal distribution with mean \( \mu \) and standard deviation \( \sigma \), and
Fig. 1. Random LQR example. (a) $\Sigma_{bb} = 0$ and varying $\Sigma_{aa}$. (b) $\Sigma_{aa} = 0$ and varying $\Sigma_{bb}$. (c) $\Sigma_{bb} = 0.64$ and varying $\Sigma_{aa}$.

our stage cost is

$$g(x,u) = x^2 + u^2.$$ 

We solve the finite-horizon problem (with zero final cost), resulting in cost-to-go functions that have the form

$$V_t(x) = k_t x^2, \quad t = 0, 1, \ldots, T.$$ 

For all of the following examples, we let $\bar{a} = 1.1, \bar{b} = 1.0, T = 50, N = 50$, and we plot the coefficient $k_t$ versus $t$ in the following three cases.

1) $a$ fixed and $b$ random: We fix $\Sigma_{aa} = 0$, and vary $\Sigma_{bb} \in \{0, 0.81, 1.44, 2.25, 2.89, 3.61, 4.41, 4.84, 5.76\}$.

The results are displayed in Fig. 1(a).

2) $a$ random and $b$ fixed: We fix $\Sigma_{bb} = 0$, and vary $\Sigma_{aa} \in \{0, 0.25, 0.49, 0.64, 0.81, 1.00, 1.21\}$.

The results are displayed in Fig. 1(b).

3) Both $a$ and $b$ random: We fix $\Sigma_{bb} = 0.64$, and vary $\Sigma_{aa} \in \{0, 0.16, 0.25, 0.36, 0.49, 0.64, 0.81\}$.

The results are displayed in Fig. 1(c).

Our results match those of [45], modulo Monte Carlo error. When the variance gets too large, the cost-to-go functions diverge to $+\infty$, as predicted by the uncertainty threshold principle, and numerically checkable by our implementation.

D. Jump LQR

Jump LQR is LQR with dynamics that jump (or switch) between modes. In infinite-horizon jump LQR, the dynamics are

$$x_{t+1} = A^s x_t + B^s u_t + e^s, \quad t = 0, 1, \ldots$$

$$s_{t+1} = i \text{ with probability } \Pi_{ij} \text{ if } s_t = j, \quad t = 0, 1, \ldots.$$ 

As in LQR, we adopt a quadratic form stage cost for simplicity. For this problem, there is an optimal policy that is affine in $x$ for each mode. We can find this policy using the algorithms described in this article. When there is no switching ($\Pi = I$), the problem reduces to $K$ separate LQRs (one for each mode). Depending on the exact problem data and distributions, the policies found with switching can be substantially different than the nonswitching policies.

E. Numerical Example

Consider the one-dimensional system, i.e., $m = n = 1$, with dynamics described by

$$x_{t+1} = 1.2 x_t + 0.1 u_t; \quad s = 1$$

$$x_{t+1} = 0.8 x_t - 0.1 u_t; \quad s = 2$$

and Markov chain switching probabilities given by

$$\Pi = \begin{bmatrix} 0.8 & 0.2 \\ 0.2 & 0.8 \end{bmatrix}.$$
Consider the following stage cost function:

\[ g(x, u) = \frac{1}{2} x^2 + \frac{1}{2} u^2. \]

We solved the undiscounted (\(\gamma = 1\)) infinite-horizon problem with 20 applications of the Bellman operator. The optimal policy for the case with switching is

\[ \phi^*(x) = \begin{cases} -2.541x & s = 1 \\ 0.919x & s = 2. \end{cases} \]

We also solved the problem with no switching, resulting in the optimal policy

\[ \phi_{\text{ind}}(x) = \begin{cases} -3.844x & s = 1 \\ 0.207x & s = 2. \end{cases} \]

The two policies are substantially different. The policies, over 100 time steps in the actual system starting at \(x_0 = (10)\) and \(s_0 = 1\), achieve an expected cost of 16.16 and 18.53, respectively (averaged over 100 simulations with the same random seed). The policy found taking into account the switching outperforms the policy that ignores the switching.

**F. Multimission LQR**

LQR can be extended to handle randomly switching costs. In multimission LQR, the mode \(s_t\) corresponds to the current cost assigned to the controller. The dynamics are the same as LQR, but the costs depend on the mode, or

\[ g^i(x, u) = \frac{1}{2} \begin{bmatrix} x \\ u \end{bmatrix}^T G^i \begin{bmatrix} x \\ u \end{bmatrix}. \]

The algorithms described in this article can be used to solve the finite or infinite-horizon stochastic control problems, and result in an affine policy for each “mission.”

**G. Numerical Example**

We apply the example mentioned above to a tracking mission. Let \(p_t \in \mathbb{R}^2\) denote the position and \(v_t \in \mathbb{R}^2\) denote the velocity of a point mass in two dimensions. The state is \(x_t = (p_t, v_t)\) and the force applied is \(u_t \in \mathbb{R}^2\). Suppose the dynamics are described by

\[
\begin{bmatrix}
1 & 0 & 0.05 & 0 \\
0 & 1 & 0 & 0.05 \\
0 & 0 & 0.98 & 0 \\
0 & 0 & 0 & 0.98
\end{bmatrix}
\begin{bmatrix}
x_t \\
u_t \\
0 \\
0
\end{bmatrix}
\begin{bmatrix}
x_t+1 \\
u_t
\end{bmatrix}
\]

For each mission, the point mass’s goal is to navigate to a target position \(d_i \in \mathbb{R}^2\) while minimizing control effort, corresponding to a stage cost

\[ g^i(x, u) = (1/2)\|p - d_i\|_2^2 + (\lambda/2)\|u\|_2^2 \]

where \(\lambda > 0\).

Suppose we have three targets given by

\[
d_1 = (-1, 5) \quad d_2 = (-1, -2.5) \quad d_3 = (1, 0)
\]

and mission switching probabilities given by

\[
\Pi = \begin{bmatrix}
0.97 & 0.0075 & 0.015 \\
0.003 & 0.97 & 0.15 \\
0.027 & 0.0225 & 0.97
\end{bmatrix}
\]

We solved the corresponding (infinite horizon) stochastic control problem with \(\lambda = 0.1, T = 50, N = 1,\) and \(\gamma = 1\). A sample run of the optimal policy for the switching and no switching problems is shown in Fig. 2. The policy that takes into account the switching does not go directly toward the targets, knowing that at any time the mission will switch and it will have to change course.

**H. Fault Tolerant LQR**

We extend LQR to the case where control inputs (or actuators) randomly stop affecting the system. Suppose a system is deterministic and described by the linear dynamics

\[ x_{t+1} = Ax_t + Bu_t \]

and we would like to model input failures, i.e., if input \(i\) has failed, \((u_t)\) has no effect on \(x_{t+1}\).

We associate each mode of the system \(s_t\) with an actuator configuration \(a_t \subseteq \{1, \ldots, m\}\), which contains the indexes of
the control inputs that have “failed.” We assume that we know what actuator configuration we are in. We can then associate each actuator configuration $a_i$ with a corresponding input matrix $B^i$, where the $j$th column of $B^i$ is defined as

$$B^i_j = \begin{cases} 0 & j \in a_i \\ b_j & \text{otherwise} \end{cases}$$

where $b_j$ is the $j$th column of $B$. We then can define a mode switching probability matrix $\Pi$, where $\Pi_{ij}$ is the probability that the system transitions from actuator configuration $a_i$ to actuator configuration $a_j$. Our system’s dynamics with actuator failures are described by

$$x_{t+1} = Ax_t + B^i x_t$$
$$s_{t+1} = i \text{ with probability } \Pi_{ij} \text{ if } s_t = j.$$  

This is an extended quadratic control problem. We also know that for each actuator configuration, the optimal policy is affine. To implement this policy, one first identifies which actuators have failed, and then applies an affine transformation to the state to get the input.

This exact problem (with quadratic form cost) was first identified and solved by Birdwell and Athans in 1977 [32] (see also Birdwell’s thesis [46]), where they derived what they call “a set of highly coupled Riccati-like matrix difference equations.” As expected, the cost-to-go functions that they derive are quadratic and the optimal policy is affine for each actuator configuration. They used about a page of algebra to show this; we immediately know this.

I. Numerical Example

We reproduce a slight modification of the example in [32]. Here our dynamics are

$$x_{t+1} = \begin{bmatrix} 2.71828 & 0 \\ 0 & 0.36788 \end{bmatrix} x_t + \begin{bmatrix} 1.71828 \\ -0.63212 \end{bmatrix} u_t.$$  

The actuator configurations are $0$, $\{1\}$, and $\{2\}$, resulting in control matrices

$$B^1 = \begin{bmatrix} 1.71828 \\ -0.63212 \end{bmatrix}, \quad B^2 = \begin{bmatrix} 0 \end{bmatrix}, \quad B^3 = \begin{bmatrix} 1.71828 \\ -0.63212 \end{bmatrix}.$$  

and

$$B^3 = \begin{bmatrix} 0 \\ 0 \end{bmatrix}.$$  

The mode switching probability matrix is

$$\Pi = \begin{bmatrix} 0.943 & 0.069 & 0.026 \\ 0.03 & 0.854 & 0.04 \\ 0.027 & 0.077 & 0.934 \end{bmatrix}.$$  

We use a stage cost $q(x, t) = \|x\|^2 + \|u\|^2$. The optimal policies are linear, given by

$$\phi^2(x) = \begin{bmatrix} 0 & 0 \\ -1.455 & -0.003 \end{bmatrix} x.$$  

$$\phi^3(x) = \begin{bmatrix} -1.462 & 0.002 \\ 0 & 0 \end{bmatrix} x.$$  

If an actuator does not affect the system, the optimal action sets this input to zero, since one incurs cost for having its input not equal to zero. (This is why the first column of $B^2$ is zero and the second column of $B^3$ is zero.) If we ignore the fact that the dynamics switch when an actuator fails, we arrive at a suboptimal policy.

J. Portfolio Allocation With Multiple Regimes

In this example, we frame the problem of designing an optimal portfolio allocation in a market that randomly switches between multiple regimes. We borrow the notation from [47].

K. Holdings

We work in a universe of $n$ financial assets. We let $h_t \in \mathbb{R}^n$ denote the (dollar-valued) holdings of our portfolio in each of those $n$ assets at the beginning of time period $t$. (We allow $(h_t)_i < 0$, which indicates that we are short selling asset $i$.) The total value of our portfolio at time $t$ is $v_t = 1^T h_t$. Our state is $h_t$.

L. Trading

At the beginning of each time period, we select a trade vector $u_t \in \mathbb{R}^n$ that denotes the dollar value of the trades to be executed. After making these trades, the investments are held constant until the next time period. The post-trade portfolio is denoted

$$h_t^+ = h_t + u_t, \quad t = 0, \ldots, T - 1$$  

with a total value $v_t^+ = 1^T h_t^+$. We have a self-financing constraint, i.e., $v_t = v_t^+$, which can be expressed as

$$1^T u_t = 0.$$  

M. Market State

We assume that the market is in one of several (fully observable) market regimes. We assign a mode $s_t \in \{1, \ldots, K\}$ to each regime. Each regime corresponds to a different return distribution and transaction costs. We use a Markov chain to model the market regime switching from time $t$ to $t + 1$.

N. Investing Dynamics

The post-trade portfolio is invested for one period. Assuming the market is in the mode $s_t$, the portfolio at the next time period is given by

$$h_{t+1} = (I + \text{diag}(r_{t+1}^s)) h_t^+$$  

where $r_{t+1}^s \in \mathbb{R}^n$ is a random vector of asset returns from time $t$ to time $t + 1$ when the market is in the mode $s_t$. The mean of the return vector for time $t$ in mode $s_t$ is denoted $\mu_{t+1}^s = E[r_{t+1}^s]$ and its covariance is denoted $\Sigma_{t+1}^s = E[(r_{t+1}^s - \mu_{t+1}^s)(r_{t+1}^s - \mu_{t+1}^s)^T]$. 

Authorized licensed use limited to: Stanford University. Downloaded on March 07,2022 at 20:22:39 UTC from IEEE Xplore. Restrictions apply.
O. Transaction Cost

The trading results in a transaction cost \( \phi^{\text{trade}}_{t,s} : \mathbb{R}^n \to \mathbb{R} \) (in dollars), which we assume to be a (diagonal) quadratic form, i.e.,

\[
\phi^{\text{trade}}_{t,s}(u_t) = u_t^T \text{diag}(b_t^s) u_t
\]

where \((b_t^s)_i \in \mathbb{R}^+\) is the coefficient of the quadratic transaction cost for asset \(i\) during time period \(t\) when the market is in the mode \(s\).

P. Returns

The portfolio return from period \(t\) to \(t+1\) when the market is in mode \(s\) is given by

\[
R_t^s = v_{t+1} - v_t - \phi^{\text{trade}}_{t,s}(u_t)
\]

\[
= 1^T (h_{t+1} - h_t) - \phi^{\text{trade}}_{t,s}(u_t)
\]

\[
= 1^T (I + \text{diag}(r_t^s)) (h_t + u_t) - h_t - \phi^{\text{trade}}_{t,s}(u_t)
\]

\[
= (r_t^s)^T x_t + 1^T u_t + (r_t^s)^T u_t - \phi^{\text{trade}}_{t,s}(u_t)
\]

\[
= (r_t^s)^T (x_t + u_t) - \phi^{\text{trade}}_{t,s}(u_t).
\]

The expected return is given by

\[
\mathbb{E}[R_t^s] = (\mu_t^s)^T (x_t + u_t) - \phi^{\text{trade}}_{t,s}(u_t).
\]

The variance of the return is given by

\[
\text{Var}[R_t^s] = (x_t + u_t)^T \Sigma_t^s (x_t + u_t).
\]

Q. Stage Cost Function

Our goal will be to maximize a weighted combination of the mean and variance of the returns, while satisfying the self-financing condition. This can be accomplished with the following (extended quadratic) stage cost function:

\[
\phi_t^s(x, u) = \begin{cases} 
-\mathbb{E}[R_t^s] + \phi^{\text{trade}}_t(u) + \gamma_t \text{Var}[R_t^s] & \text{for } t \leq T \\
+\infty & \text{for } t > T
\end{cases}
\]

for some parameter \(\gamma_t > 0\) that trades off return and risk.

The abovementioned problem can be solved with the algorithm described in this article by providing an oracle that provides samples of \(r_t^s\) for all \(t, s\) (we can estimate the mean and covariance from this), the transaction cost vector \(b_t^s\) for all \(t, s\), and the mode switching probability matrix \(\Pi_t\) for all \(t\). The optimal trade vector when the market is in mode \(s\) will be an affine function of the holdings, i.e.,

\[
u_t = K_t^s x_t + k_t^s.
\]

It turns out that the optimal policies can be written in the following more interpretable form:

\[
u_t = K_t^{s_t} (h_t - (h_t)^{s_t})
\]

where \((h_t)^{s_t} = -(K_t^{s_t})^T k_t^{s_t}\) is the desired holdings vector in the regime \(s_t\). To select a trade vector, we calculate the difference between our current holdings and our desired holding, and then multiply that difference by a feedback gain matrix.

To the best of authors’ knowledge, this application has not yet appeared in the literature.

R. Numerical Example

We gathered the daily returns from October 2013 to October 2018 of \(n = m = 6\) popular exchange traded funds (ETFs).

For the market regime, we used the daily rate of change of the CBOE Volatility Index (VIX), which approximates the market’s expectation of 30-day volatility. We gathered the daily opening price of the VIX and calculated its daily rate of change, which we refer to as dVIX. We segmented dVIX into \(K = 5\) numerical ranges defined by the endpoints

\[
(-0.09, -0.017, -0.003, 0.003, 0.03, 0.287)
\]

and define the range that it is in at time \(t\) as the regime \(s_t \in \{1, \ldots, K\}\). We then calculated the empirical probabilities of switching between each market regime (values of dVIX), resulting in the following mode switching probability matrix:

\[
\Pi = \begin{bmatrix}
0.159 & 0.123 & 0.146 & 0.189 & 0.282 \\
0.242 & 0.291 & 0.299 & 0.276 & 0.197 \\
0.108 & 0.215 & 0.201 & 0.156 & 0.155 \\
0.357 & 0.318 & 0.305 & 0.319 & 0.225 \\
0.134 & 0.054 & 0.049 & 0.06 & 0.141
\end{bmatrix}
\]

For each regime, we gathered all of the days where the market was in that regime and fit a multivariate log-normal distribution to \(1 + r_t^s\) for the five ETFs.

Using these distributions and mode switching probabilities, we solved an instance of the portfolio allocation problem with a time horizon of \(T = 30\), \(N = 50\), \(\gamma_t = 1 \times 10^{-3}\), \(b = p_0 \cdot 1 \times 10^{-7}\) (where \(p_0 \in \mathbb{R}^n\) is the price of the assets at the final day of the ETF data), and no final cost. We then simulated the system several times (using different random seeds) starting in the initial state \(h_0 = (1000)\) and \(s_0 = 3\). Fig. 3 displays various quantities over time from the simulations.

S. Optimal Retirement

The goal in retirement planning is to devise an investment allocation and consumption schedule for the rest of ones life in order to maximize personal utility. In this section, we frame retirement planning as an extended quadratic control problem, with the state being the investor’s wealth, the input being the allocation over various financial assets (and an amount to consume), the investor’s terminal utility, and the mode corresponding to whether the investor is alive or deceased.

We let the time period \(t\) represent a (calendar) year. At the beginning of year \(t\), the mode \(s_t\) corresponds to whether the investor is alive (\(s_t = 1\)) or deceased (\(s_t = 2\)). If the investor is alive at the beginning of year \(t\), either they pass away (\(s_{t+1} = 2\)) with probability \(p_t\), or they continue to live (\(s_{t+1} = 1\)) with probability \(1 - p_t\). The deceased mode is absorbing, i.e., if the investor is deceased at year \(t\), they stay deceased at year \(t + 1\). The mode dynamics is given by the mode switching probability
Fig. 3. (a) Total value of the portfolio versus time (in days) over fifteen simulations from the same initial condition. (b) Portfolio allocation \((h_t/v_t)\) versus time (in days) for one simulation. (c) Histogram of normalized portfolio return over thirty days of trading over 1000 simulations. The average return was 1.72% with a standard deviation of 5.53%. (d) Market regime versus time for the same simulation as (b).

\[
\Pi_t = \begin{bmatrix} 1 - p_t & 0 \\ p_t & 1 \end{bmatrix}
\]

The investor’s wealth \(W_t \in \mathbb{R}\) is the wealth (in dollars) of the investor at the beginning of year \(t\). We operate in a universe of \(m\) financial assets that the investor may choose to invest in. At the beginning of year \(t\), the investor allocates their wealth across \(m\) financial assets by specifying a holdings vector \(u_t \in \mathbb{R}^m\), where \((u_t)_i\) is the holdings amount (in dollars) of asset \(i\) \((u_t)_i < 0\) corresponds to shorting the asset. The amount that the investor does not invest

\[C_t = W_t - 1^T u_t\]

is consumed if the investor is alive and bequeathed (i.e., left to beneficiaries by a will) if the investor is deceased. If the investor consumes \(C_t\) during year \(t\), they receive \(U_t(C_t)\) utility, where \(U_t : \mathbb{R} \to \mathbb{R}\) is a concave quadratic utility function for consumption. If the investor bequeaths \(C_t\), they receive \(B(C_t)\) utility, where \(B : \mathbb{R} \to \mathbb{R}\) is a concave quadratic utility function for bequeathing. (We enforce that all of the investor’s wealth is bequeathed when they die via the constraint that \(u = 0\) when \(s = 2\).)

The investor’s wealth at year \(t + 1\) is

\[W_{t+1} = \begin{cases} r_t^T u_t & s = 1 \\ 0 & s = 2 \end{cases}\]

where \(r_t \in \mathbb{R}^m\) is a random total return vector for the financial assets over year \(t\), with \(\mathbb{E}[r_t] = \mu_t\) and \(\text{Cov}[r_t] = \Sigma_t\). The variance of the investor’s wealth at year \(t + 1\), assuming they are alive, is

\[\text{Var}(W_{t+1}) = u_t^T \Sigma_t u_t.\]

Our goal is to maximize utility, while minimizing risk, resulting in the stage cost functions

\[g^1_t(W, u) = -U_t(C) + \gamma u^T \Sigma_t u\]

\[g^2_t(W, u) = -B(C) + \begin{cases} 0 & u = 0 \\ +\infty & \text{otherwise} \end{cases}\]

We ignore transaction costs.
It is worth noting that this problem is small enough to be discretized and solved exactly (with up to 5 or 6 assets) with any dynamics and cost. So this example is just an illustration, and it is only sensible to use extended quadratic control when there are many assets.

**T. Numerical Example**

We gathered inflation-adjusted yearly returns for \( m = 3 \) assets: the S&P 500, 3-month treasury bills, and 10-year treasury bonds over the past 81 years (1938 – 2018) [48]. We fit a multivariate log-normal distribution to the returns.

The mean and covariance of \( r_t \) are roughly

\[
\mathbb{E}[r_t] = \begin{bmatrix} 1.09 \\ 1.00 \\ 1.02 \end{bmatrix}, \quad \text{Cov}[r_t] = \begin{bmatrix} 0.0316 & 0.0008 & 0 \\ 0.0008 & 0.0014 & 0.0014 \\ 0 & 0.0014 & 0.0067 \end{bmatrix}.
\]

For mortality rates, we use the Social Security actuarial life table [49], which gives the death probability (probability of dying in one year) for each age, averaged across the United States’s population.

We use the utility functions

\[
U_t(C) = -\frac{1}{2} (0.2) C^2 + 20C, \quad B(C) = -\frac{1}{2} (0.002) C^2 + 4C.
\]

Here, \( U_t(0) = B(0) = 0 \), the maximum of \( U_t \) is at 100 where \( U_t(100) = 1000 \), and the maximum of \( B \) is at 2000 where \( B(2000) = 4000 \). The utility functions were designed so that the investor ideally consumes \$100k\ every year, and bequeaths \$2m\.

We use a risk aversion parameter \( \gamma = 1 \times 10^{-2} \).

The optimal policy has the form

\[
u_t = K_t W + k_t
\]

where \( K_t \in \mathbb{R}^{3 \times 1} \) and \( k_t \in \mathbb{R}^3 \). Therefore, the consumption amount during year \( t \) is equal to

\[
C_t = W_t - 1^T u_t = W_t - 1^T (K_t W + k_t) = (1 - 1^T K_t) W_t - 1^T k_t.
\]

We can rewrite this in the more interpretable form

\[
u_t = f_t(W_t - 2000) + g_t.
\]

Here, \((W_t - 2000)\) is the deficit or excess wealth the investor has as compared to the optimal bequest amount, \( f_t \) is unit-less, and \( g_t \) is in units thousands of dollars.

Fig. 4 shows \( f_t \) versus \( t \) and Fig. 5 shows \( g_t \) versus \( t \), starting from age 60.

We simulated (the remainder of) an investor’s life, starting at age 60 with \$3m\, using the optimal policy found by our algorithm, over 500 random seeds. Fig. 6 shows wealth versus age over the first 10 random seeds. Fig. 7 shows the fraction of the investor’s wealth invested in the S&P 500 over age, over the same 10 random seeds. It appears that the investor seeks a riskier allocation as they age, which is counter-intuitive, since one would expect the opposite.

Fig. 8 shows a histogram of consumption amounts, over all 500 random seeds. The investor rarely consumes over 100 \$; if they do, this is likely because they do not want to bequeath too much (this is a limitation of quadratic utility functions). Fig. 9 shows a histogram of bequest amounts, over all 500 random seeds. The median bequest amount was \$1.747m. 
the solution. There is no clean expression for the optimal policy, however computing it can be reduced to iteratively performing several simple linear algebraic operations on the coefficients of extended quadratic functions. We have also developed an implementation that exactly solves (modulo how expectation is performed) these problems using these operations defined on extended quadratics, given access only to a sampling oracle. We demonstrate the usefulness of such an approach via many applications, some of which, to the best of authors’ knowledge, have not appeared yet in the literature.

VII. CONCLUSION

It has been about 60 years since the invention of LQR. Since its invention, everyone has known that LQR problems can be solved exactly. Many extensions, some which maintain tractability, and some that do not, have been proposed over the years. In this article, we have collected the tractable extensions, unified them as a single general class of problems, and proven the form of
